Supporting Structures for Offshore Production Plants (Fig. 61). The production platforms used for offshore oil and gas production are of the same type as those for the drilling rigs of fixed platforms and semisubmersibles. The first platforms were built as wooden structures, but since 1940 they have been constructed only of steel or concrete. All submersed steel structures require corrosion protection in order to ensure a sufficient service life. For this, direct protection paint and/or galvanization is used and in addition cathodic protection devices feeding external current or sacrificial anodes are applied.

In the Norwegian and British sectors of the North Sea, several large concrete structures have been set down on the sea bottom. These consist of three hollow conical bodies of concrete, constructed on the sliding molding principle, that contain, as an upper annex, multistorey production installations and personnel accommodation; the derrick also is arranged there.

From these large structures, a fairly large number of deflected holes are sunk. Two legs contain the production casing of the wells. The third leg receives essentially the supply and line system. The base of the structure is provided with a large number of concrete tanks in which the crude oil, salt water, and other products are stored. The first stages of the structures were built in Norwegian fjords, on a construction deck raised on sheet piles. Then, when the structure had reached a certain stage, the installations were floated off and towed into deeper water, in order to allow immersion during the further weight increase resulting from concreting to the final height. The maximum total height of these installations in the Brent and Statfjord fields is 250 m at a water depth down to 175 m. A small wave pressure and short installation times at the location (no ramming work) were reasons for constructing such structures, which, however, can be set down only on a suitably firm sea bottom. The largest offshore platform in the world is 271 m high and has been installed in the Norwegian Statfjord field.

Offshore Well Equipment. An important technical problem in drilling at sea is the effect of the heaving swell and of the current on the sea bottom. Movements and vibrations of the drilling rig in relation to the pipe strings leading to the sea bed (riser and drill string) must be avoided. However, these undesirable effects cannot completely be removed especially on floating drilling rigs (semisubmersible and drillship). Devices are used to combat these difficulties. They are installed in the hoist installations and in the casing string (riser). For wells in *shallow water areas* there are no longer any special problems. Here completion arrangements can be employed which are also in use on land, with casing held in a "well protector" and led out above the surface of the sea.

However, in *fairly deep water* and in the area of shipping lanes, underwater completion must be used. This was first applied in 1943 in the 11.5 m deep water of Lake Erie. Meanwhile, such systems, usually remote-controlled, have been installed in a great variety of sea areas of the world. Installations that cannot be reached by divers are not yet in use. Two types of completion exist: *wet completion,* in which all the components are in contact with the sea, and *dry completion,* in which the components are in a pressure chamber under atmospheric conditions, so that the personnel can carry out assembly and maintenance of the installation by "submarine passenger ferry." The criteria for the selection of suitable completion include water depth, weather conditions, areas with shipping lanes, icebergs, mechanical properties of the seabottom and the possibility of sediments wandering at sea bottom.

The use of divers, drilling rigs, or workover ships is required for necessary repairs, possible replacement of the Christmas tree and the tubing, and workover operations.

Logistics. As soon as the production of oil and gas in the offshore sector is taken up, provision must be made for the transportation of these products. Underwater pipelines and ships are primarily used. An essential prerequisite for the

smooth and secure operation of offshore drilling and production activities is the existence of a land base. The land base provides the maintenance service, all supplies of materials, as well as the catering, intelligence, and rescue services, and usually the exchange of personnel by helicopter, etc.

1. Introduction

Rhenium (Re) is present in the earth's crust at a very low concentration (ca. 7×10^{-8} %, 0.7 ppm). The element was not discovered until 1925, when TACKE, NODDACK, and BERG observed its X-ray spectrum in concentrates and compounds obtained from the beneficiation of columbite [5].

The discoverers isolated the first gram of rhenium from 660 kg of Norwegian molybdenite (MoS_2), which contained 2 – 4 ppm Re [6]. Rhenium is the most recently discovered refractory metal; it is a member of the group of high-melting metals that includes molybdenum, tungsten, niobium, and tantalum. It has the second highest melting point of all metals (3453 K).

Industrial production of rhenium began in the 1930s at Kali Werke Aschersleben in the Harz region [7], and also at H. C. Starck (HCST), formerly Gebr. Borchers AG, in Goslar. The raw material consisted of furnace bottoms, byproducts from the treatment of Mansfeld copper schists. The furnace bottoms were digested by fusion with sodium sulfate [8]. Then, after a complicated chemical separation process, rhenium was isolated as potassium perrhenate, which was reduced with hydrogen to give the impure metal.

An important advance in rhenium technology was the production of the element from flue dusts from the roasting of molybdenite [9]. The amount recovered from the dusts was, however, only 10 – 15 % of the total Re content of the MoS_2 concentrate. The introduction of accurate analytical methods [10] enabled material balances for rhenium extraction to be established. These showed that most of the rhenium was lost up the stack, and only a small amount remained in the flue dust or in the roasted product. The flue gas was therefore scrubbed intensively to ensure that the volatile oxides of rhenium were recovered when the molybdenite concentrate was roasted [11, 12].

2. Properties

Physical Properties. Rhenium [*7440-15-5*] has the electronic configuration [Xe]$4f^{14}5d^5 6s^2$, and consists of the natural isotopes ^{185}Re (37.07 %) and ^{187}Re (62.93 %, β-emitter with a half-life of 10^{11} years). Fused or sintered rhenium has a silvery white luster, and the powdered metal is silver gray. It has a hexagonal close-packed structure (type A 3), with $a_0 = 276$ pm and $c_0 = 446$ pm. Rhenium retains this lattice up to its melting point and hence does not undergo a ductile – brittle transformation, in contrast to other refractory metals.

Other physical data are listed below:

Atomic number	75
Relative atomic mass A_r	186.207
Density (20 °C)	21.0 g/cm^3
Metallic radius	137 pm
Ionic radius (VII)	53 pm
Melting point	3453 K (3180 °C)
Boiling point	6143 K (5870 °C)
Heat of fusion	33 kJ/mol
Heat of sublimation	
ΔH_B (monatomic gas)	+779 (± 8) kJ/mol
Enthalpy of formation of Re_2O_7	−1241 kJ/mol
Electrical conductivity	0.051 $\mu\Omega^{-1}$ cm^{-1}
Specific resistivity (20 °C)	19.3 $\mu\Omega \cdot$ cm
Superconductivity	1.699 K
Tensile strength (20 °C, annealed)	12 MPa
Modulus of elasticity (20 °C)	459.9 GPa
Recrystallization temperature (depending on degree of working)	1573 – 2073 K

Chemical Properties. Rhenium is a very heat-resistant metal, provided it does not come in contact with oxidizing agents. It is practically insoluble in hydrochloric and hydrofluoric acids. In oxidizing acids, it dissolves to form perrhenic acid (E^0 for Re/ReO_2: 0.251 V).

Rhenium forms volatile oxides with oxygen at high temperature. In air at 350 °C, the heptoxide, Re_2O_7, is formed. The rate of oxidation increases with increasing air flow rate. The stability of rhenium metal components is limited due to oxide formation even below 0.133 Pa [13]. When rhenium is heated with fluorine or chlorine, the fluorides or chlorides are formed. Rhenium reacts with silicon, boron, and phosphorus at elevated temperature to form silicides, borides, and phosphides.

3. Occurrence and Raw Materials

3.1. Molybdenite

Molybdenite, MoS_2 [*1317-33-5*], especially from porphyry copper ore deposits, is the preferred host mineral for rhenium, which isomorphically replaces molybdenum in the MoS_2 lattice. The copper – molybdenum porphyry ores contain 0.3 – 1.6 % Cu and 0.01 – 0.05 % Mo. The sulfides of copper and molybdenum are concentrated and separated by flotation, giving a rhenium content in the MoS_2 concentrates of several hundred parts per million.

Rhenium contents (in ppm) of selected molybdenum concentrates of various origins are as follows:

Canada	
Island Copper	700 – 1300
HVC	200 – 400
Endako	< 100
United States	
Pinto Valley	1500 – 2000
Magma San Manuel	800
Bagdad	350
Sierrita	180
Bingham Canyon	250
Climax	30
Henderson	20
Mexico	
La Caridad	570
Peru	
Cuajone	580
Toquepala	600
Chile	
Chuquicamata	300
El Salvador	600
El Teniente	400
Iran	
Sar Chesmeh	800

World rhenium reserves [14] (in t Re) are

Canada	32
Chile	1306
Peru	45
CIS	594
United States	386
Others	91
World total	2453

In copper concentrates, the rhenium content is 10 – 50 ppm, the molybdenum content 200 – 600 ppm. Copper concentrates are therefore a useful source of rhenium.

3.2. Recovery from Spent Catalysts and Alloys

Platinum – rhenium catalysts are used in the petroleum industry in the reforming process. When their activity is too low even after regeneration, the catalysts must be replaced. Valuable metals are recovered by dissolving the carrier (Al_2O_3) in sodium hydroxide solution or sulfuric acid. Platinum remains in the residue, from which it can be recovered. Rhenium, which goes into solution, can be recovered by solid or liquid ion exchangers [15].

In addition to this hydrometallurgical procedure, a pyrometallurgical process (fusion) allows rapid concentration of the valuable metals [16]. The resulting alloys are treated by dissolution and separation processes.

The high economic value of the WRe, MoRe, and rhenium- containing superalloys means that scrap alloys of these compositions must be processed. The following processes are suitable:

1) Oxidation by atmospheric oxygen to form WO_3 and Re_2O_7 (*bp* 362 °C), which are separated by sublimation and distillation [17]
2) Fusion with NaOH and oxidizing agents such as $NaNO_3$ and $NaNO_2$ [18]

These initial operations are followed by isolation of the elements and crystallization of their salts.

4. Production

4.1. Recovery of Rhenium from Flue Gases in Molybdenite Roasting

Porphyry copper ores containing 0.3 – 1.6 % Cu and 0.01 – 0.05 % Mo are ground and concentrated by flotation (→ Molybdenum and Molybdenum Compounds, Chap. 4.1.). Further treatment leads to almost quantitative recovery of molybdenite.

When molybdenite (90 – 95 % MoS_2, remainder: SiO_2, Cu, Fe, etc.) is roasted at 500 – 700 °C to produce technical-grade molybdenum trioxide, MoO_3 [*1313-27-5*], rhenium heptoxide, Re_2O_7 [*1314-68-7*], sublimes due to its high vapor pressure, and escapes with the flue gases. The vapor pressure curves of some oxides and sulfides of rhenium and molybdenum are given in Figure 1 [19].

Figure 1. Vapor pressure of some oxides and sulfides of rhenium and molybdenum

The flue gases also contain sulfur dioxide, small amounts of sulfur trioxide, selenium dioxide, and large amounts of dust (MoO_3, MoO_2, and MoS_2). This dust can be recovered (> 99 %) in high-temperature electrostatic filters and recycled to the roasting process. In the final gas scrubbing operation, the remaining dust fraction, rhenium heptoxide, selenium dioxide, sulfur trioxide, and some of the sulfur dioxide are removed from the flue gas. The scrubbing liquor is recirculated to increase the rhenium concentration, allowing the subsequent process stages to be operated economically.

The compound Re_2O_7 is readily soluble in water, forming $HReO_4$, so that the recovery of rhenium from the flue gases is > 90 %. Multistage pressure jet (venturi) scrubbers enable high rhenium recovery efficiencies to be achieved, effectively removing the finest dust fractions and causing rhenium oxides to be absorbed.

The venturi system operates with a pressure difference of 30 hPa in the first stage and 150 hPa in the second stage. The mist formed in the venturi washing process is trapped in a packed tower. This intensive gas purification produces waste gases that contain very pure SO_2, which can be used for sulfuric acid production [11]. The recovery of rhenium from the flue gases in the roasting of molybdenite is shown schematically in Figure 2.

The roasted molybdenum concentrates are used mainly to produce MoO_3 for direct use in metallurgy (production of ferromolybdenum) and in molybdenum chemistry (→ Molybdenum and Molybdenum Compounds). For economic reasons, optimum conditions for rhenium recovery cannot always be maintained (temperature, air excess, etc.). The yield of rhenium is also limited by various impurities in the concentrates, especially alkali-metal and alkaline-earth elements, which form nonvolatile stable perrhenates under roasting conditions.

Other possible processes for the treatment of molybdenum concentrates include electrooxidation [20] and treatment with O_2 or NH_3 at high temperature and pressure [21]. Yields of Mo and Re are ca. 98 %. These processes have not been used thus far on an industrial scale.

a) Roasting furnace; b) Dust chamber; c) Electrostatic filter; d) Venturi scrubbers; e) Ventilator; f) Secondary washer; g) SO_2 conversion; h) Stack

4.2. Production of Pure Rhenium Compounds from Gas Scrubbing Liquors

Gas scrubbing liquors contain sulfuric acid and, typically, rhenium at 0.2 – 1.5 g/L. After removal of the solid constituents such as molybdenum oxides, sulfides, and selenium, rhenium can be precipitated as its sparingly soluble sulfide Re_2S_7 [*12038-67-4*], or by cementation on iron or zinc. It can then be concentrated further.

However, the use of ion exchangers in solid or liquid form is preferable for recovering and concentrating rhenium. Primary, secondary, and tertiary long- chain amines, dissolved in organic solvents such as kerosene, can be used to extract rhenium and molybdenum at pH 1 – 2. At higher pH, quaternary amines are more effective [22]. Separation of molybdenum from rhenium can be achieved by extraction at an optimum pH. Alternatively, both elements can be extracted from acidic solution and then separated by selective stripping with ammonia at different pH values [23].

Rhenium in neutral, alkaline, or sulfuric acid solution can be fixed by strongly basic solid ion exchangers. The molybdate ion is less strongly bound to the ion exchanger than the perrhenate ion, enabling the molybdenum to be removed by a displacement reaction. Rhenium can be eluted from the ion-exchange resin by strong mineral acids, especially perchloric acid, or ammonium thiocyanate [24].

Figure 3. Rhenium production

Technical-grade ammonium perrhenate is produced by crystallization from the eluate solution. Further purification is carried out by recrystallization.

Solvent extraction, combined with the use of solid ion exchangers or crystallization, can be used to produce pure or highly pure ammonium perrhenate, which is the starting material for the production of many rhenium compounds as well as the metal [25]. A schematic of rhenium production is given in Figure 3.

Another method of rhenium production consists of solvent extraction combined with electrowinning of the rhenium from perchlorate solutions [26].

4.3. Production of Rhenium Metal Powder and Pellets

Rhenium powder [*7440-15-5*] can be produced by the reduction of pure ammonium perrhenate NH_4ReO_4 [*13598-65-7*] in a stream of hydrogen. This reduction is usually carried out in two stages:

1) Reduction at 300 – 350 °C to form ReO_2
2) Reduction of the ReO_2 to Re metal powder at 800 °C

The desired properties of the metal powder, such as grain size and surface area,can be achieved by adjustment of the reduction parameters.

In a further stage, the rhenium metal powder with added compaction agents is compressed into pellets and then sintered at ca. 1000 – 1500 °C under an atmosphere of hydrogen. To produce large workpieces, the powdered metal is charged into rubber containers, compressed isostatically at ca. 500 MPa, and then sintered. Rhenium can be produced at almost its theoretical density by hot isostatic pressing (HIP) and by electron-beam or electric-arc melting.

Rhenium has very high strength at high temperature, as well as extremely good ductility and cold working properties. It is therefore a very useful high-temperature material. In some applications, the useful properties of rhenium can best be realized by chemical vapor deposition (CVD) [27]. Plasma coating with spheroidized rhenium metal powder is another possibility, producing dense rhenium coatings when combined with a sintering operation.

5. Rhenium as an Alloying Component

When rhenium is used as an alloying component with the metals tungsten and molybdenum, which are difficult to work, ductility and strength are improved [28]. This is caused by alloy softening, which is defined as the reduction in the yield stress or hardness at low temperature. This effect is observed especially in body-centered cubic alloys. In addition to the improvement in ductility at low temperature, the strength at high temperature increases [29]. Tungsten – rhenium alloys containing 25 – 30 % Re have good cold ductility [30]. As indicated in Figure 4, rhenium is very soluble in tungsten, its solubility reaching 28 wt % at 1600 °C and 37 wt % at 3000 °C. Tungsten is also soluble in rhenium: 11 wt % at 1600 °C and 20 wt % at 2825 °C. Besides a tetragonal σ-phase, a cubic χ-phase exists in a very narrow range in the W – Re system [31].

Figure 4. Tungsten – rhenium phase diagram [31]

The poor welding properties of common molybdenum alloys limit their use in high-temperature applications. The addition of rhenium enables these alloys to be welded and used as construction materials. Molybdenum – rhenium alloys containing up to 50 % Re show high tensile strength and good elongation over the temperature range 0 – 1800 °C [32].

Superalloys must have not only high strength, but also good corrosion resistance at elevated

temperature. They may be divided into three groups: nickel-base alloys, cobalt-base alloys, and iron (nickel)-base alloys.

Other typical alloying elements include chromium, molybdenum, tungsten, niobium, tantalum, aluminum, titanium, boron, and zircon. The addition 1 – 3 % Re to a nickel-base alloy improves its toughness at high temperature and prevents fatigue fracture [33].

6. Uses

Rhenium in the form of the powdered metal or pellets is incorporated into alloys by various methods. The W – Re and Mo – Re alloys are used mainly in the manufacture of thermoelements. Other uses include semiconductors, heating elements, electrical and electronic applications, high-temperature welding rods, and metallic coatings [34].

Tungsten – rhenium alloys (W5Re, W10Re) are used in the manufacture of rotating X-ray anodes (Fig. 5). For normal X-ray diagnosis, composite anodes, consisting of a very hard molybdenum base with an annular W – Re coating, are used. Computer tomography requires larger anodes, made by using a hybrid metal – graphite construction combined with a W – Re coating [35]. An alternative technique is to deposit the metals or alloys by CVD or PVD processes [36].

Figure 5. Rotating X-ray anode

Nickel-base alloys containing 1 – 3 wt % Re are used mainly in the production of aircraft turbine blades. They are monocrystalline and have high strength and resistance to oxidation. When these turbine blades are used in the hot zones of an engine, operating temperature can be increased, giving higher efficiency (lower fuel consumption). Similar effects are achieved by coating the gas turbine blades with rheniumcontaining (1 – 20 % Re) MCrAlY alloys [37].

7. Rhenium Compounds

Rhenium closely resembles its neighbors in the sixth row (W, Os) and molybdenum (diagonal relationship) in its physical properties; many chemical parallels also exist. Eleven oxidation states of rhenium have been described [38]. In the most important rhenium compounds such as perrhenic acid, the perrhenates, and dirhenium heptoxide, rhenium has the oxidation state + 7. It exhibits its lowest oxidation states (as low as – 3) in carbonyl complexes.

7.1. Oxides and Chalcogenides

The yellow hygroscopic rhenium(VII) oxide, Re_2O_7 [*1314-68-7*], is the most stable oxide of rhenium. It is formed from rhenium metal powder or other rhenium oxides in dry air or an oxygen atmosphere above 350 °C. The oxide Re_2O_7 is readily soluble in water, forming the colorless perrhenic acid, $HReO_4$ [*13768-11-1*], which is pale yellow at high concentration.

Perrhenic acid forms salts ($MReO_4$) with a tetrahedral ReO_4^- ion. Ammonium perrhenate, NH_4ReO_4, is an important starting material, which can be reduced to Re metal and used for the production of many other rhenium compounds. The preparation of some rhenium compounds is shown in Figure 6. When Re_2O_7 is heated with rhenium powder, the oxides ReO_3 [*1314-28-9*], Re_2O_5 [*12165-05-8*], ReO_2 [*1314-28-9*], and Re_2O_3 [*12060-05-8*] are formed.

In Re_2O_7, ReO_4 tetrahedra and ReO_6 octahedra are linked alternately at their corners. ReO_3 disproportionates on heating to form Re_2O_7 and ReO_2. The bluish black rhenium(IV) oxide, ReO_2, which is insoluble in water, has a distorted

Figure 6. Synthesis of rhenium compounds

rutile structure and disproportionates at 900 °C into Re_2O_7 and metallic Re.

With sulfur, rhenium forms Re_2S_7 [*12038-67-4*], ReS_3 [*12166-08-4*], and ReS_2 [*12038-63-0*]. The black rhenium(VII) sulfide is formed when hydrogen sulfide is passed into acidic solutions of perrhenates. Reduction of Re_2S_7 by hydrogen produces ReS_3. The most stable sulfide ReS_2 is formed by the thermal decomposition of Re_2S_7 or by heating the elements together. The structure of ReS_2 (trigonal prismatic) is isomorphous with the rhombohedral modification of MoS_2 [38].

Table 1 lists the properties of some oxides and sulfides of rhenium.

Ammonium perrhenate reacts with aqueous ammonium polysulfide to form $(NH_4)_2(Re_2S_{16})$, a polynuclear sulfide having a metal – metal bond with marked double-bond character [39].

7.2. Halides

The most important rhenium halides can be prepared from the elements (see Fig. 6). Rhenium(VII) fluoride, ReF_7 [*17029-21-9*], is the highest halide. It is formed at 400 °C under slight pressure. Rhenium(VI) fluoride, ReF_6 [*10049-17-9*], is formed from the elements at 125 °C. Rhenium(V) fluoride, ReF_5 [*30937-52-1*], and rhenium(IV) fluoride, ReF_4 [*15192-42-4*], can be prepared by reduction of ReF_6. Suitable reducing agents include H_2, metallic Re, SO_2, and Zn.

Rhenium pentachloride, Re_2Cl_{10} [*39368-69-9*], is an important starting material for the synthesis of other rhenium compounds. It is formed from the elements at 500 °C. In the crystal, $ReCl_6$ octahedra form edge-sharing dimers. Rhenium (III) chloride, Re_3Cl_9 [*14973-59-2*], can be produced by ther-

Table 1. Properties of some rhenium oxides and sulfides[38]

Compound	*mp/bp*, °C	Structure	Oxidation state
Re_2O_7	300/360	alternating tetrahedra and octahedra	VII

Re_2S_7	> 250 (decomp.) → ReS_2 + S		VII
ReS_2	1000 (decomp.) → Re + S	trigonal prismatic	IV

mal decomposition of the pentachloride. All rhenium(III) chlorides, bromides, and iodides contain the Re_3X_9 unit with Re_3 metal clusters.

$ReBr_3$ [*13569-49-8*] or $ReCl_3$ reacts with aqueous solutions of HBr to form $ReBr_3 \cdot \frac{2}{3} H_2O$. Single crystals can be obtained by evaporation of the solution [40]. Rhenium(IV) bromide, $ReBr_4$ [*36753-03-4*], and ReI_4 [*59301-47-2*] are formed by the reaction of $HReO_4$ with HBr or HI.

Some properties of rhenium halides are given in Table 2 [38]. A large number of complex halides and oxyhalides of rhenium are known [41]. In the latter, rhenium is linked to oxygen by both single and double bonds. With nitrogen, triple, double, and single bonds are known [42].

7.3. Carbonyls and Organorhenium Compounds

Rhenium carbonyl, $Re_2(CO)_{10}$ [*14285-68-8*], is formed by the reaction of CO with Re_2O_7 or Re_2S_7 at elevated pressure and temperature (20 MPa, 250 °C). It forms colorless crystals (*mp* 177 °C) and sublimes in vacuum. From the binary rhenium carbonyl, many cluster carbonyls, carbonyl hydrides, and complexes with a wide range of ligands in various oxidation states can be prepared [43].

A large number of organorhenium compounds with a wide range of structures, properties, and reactivities are now known [44]. The syntheses of hexamethylrhenium, $Re(CH_3)_6$ [*56090-02-9*] [45], and of the half-sandwich complex, $[(\eta^5\text{-}C_5Me_5)ReO_3]$ [*90695-83-3*] [46], have enabled new model substances for homogeneous organometallic catalysis to be prepared.

8. Uses of Rhenium Compounds

Rhenium compounds are used in various areas of homogeneous and heterogeneous catalysis in petrochemistry, the pharmaceutical industry, and organic synthesis (e.g., alkylation, dehydroisomerization, dealkylation, isomerization, dehydrochlorination, hydrogenation, dehydrogenation, dehydrocyclization, oxidation, and reforming [47]).

Reforming (→ Benzene, Chap. 5.2.1.; → Oil Refining, Chap. 3.4.) is an important part of petroleum processing. It is used in the production of unleaded antiknock fuels for internal combustion engines and aromatic hydrocarbons for various syntheses [48]. Originally, molybdenum oxide was used for reforming, but it was soon found that platinum on aluminum oxide (Al_2O_3) had better catalytic properties. An increase in catalytic activity, selectivity, and particularly stability was achieved with the development of platinum – rhenium catalysts. The production of Pt – Re bimetallic catalysts by Chevron and UOP began in 1968 (Rheniform process). The rhenium components were solutions of NH_4ReO_4 or $HReO_4$. Multimetallic catalysts such as platinum – rhenium – indium have been developed from the earlier bimetallic catalysts [49]. The reforming process is still the most important catalytic application of rhenium compounds. In 1990, 45 % of rhenium consumption in the United States was for this process [14].

New rhenium compounds such as methyltrioxorhenium, CH_3ReO_3 [*70197-13-6*], which can be produced fairly simply from Re_2O_7 and tetramethyltin, exhibit catalytic activity in the synthesis of alkenes (alkene metathesis), alkene oxidation, and alkenation of aldehydes [50].

Basic research in the field of rhenium compounds is expected to lead to the discovery of further catalytic properties of known rhenium

Table 2. Rhenium halides

Oxidation state	Fluorides	Chlorides	Bromides	Iodides
VII	ReF_7 yellow *mp* 48.3 °C *bp* 73.7 °C			
VI	ReF_6 yellow *mp* 18.5 °C *bp* 33.7 °C	$ReCl_6$ brown – green *mp* 29 °C		
V	ReF_5 yellow – green *mp* 48 °C *bp* 221 °C (extrapolated)	$ReCl_5$ black – brown *mp* 220 °C	$ReBr_5$ dark brown 110 °C (decomp.)	
IV	ReF_4 blue *mp* 124.5 °C sublimes 300 °C	$ReCl_4$ black – violet 300 °C (decomp.)	$ReBr_4$	ReI_4 (decomp. > room temperature)
III		$(ReCl_3)_3$ dark red sublimes 500 °C (decomp.)	$(ReBr_3)_3$ red – brown	$(ReI_3)_3$ black (decomp. on heating)

compounds and of compounds as yet undiscovered.

9. Analysis

The analytical chemistry of rhenium includes the determination of rhenium in raw materials and intermediates, and the determination of trace impurities in high-purity rhenium products.

Rhenium can be determined by various analytical methods after separation by selective precipitation, distillation, extraction, and ion exchange. W. Geilmann and H. Bode carried out important research into the analysis of rhenium in the 1940s and 1950s [51]. The most important practical application is the rapid and convenient determination of small amounts of rhenium in the presence of large amounts of molybdenum, which invariably accompanies it. After treatment of a sample with alkali, rhenium is determined in the Re(VII) state as the perrhenate ion. The accompanying elements are separated and masked, and Re(VII) is then precipitated by addition of the tetraphenylarsonium cation and determined gravimetrically [52]. In acidic solution in the presence of $SnCl_2$, Re(VII) forms colored chelates with oximes and thiocyanates, which are extracted and determined by spectrophotometry [53]. Rhenium can be determined by atomic absorption spectrometry using the resonance line at 346.047 nm. Analysis of solutions by emission spectrometry uses the lines at 346.047 and 346.473 nm [54]. Polarographic methods are also available [55].

The determination of trace elements in high-purity rhenium products, such as NH_4ReO_4 or rhenium metal, is carried out by combustion analysis (C), hot extraction by carrier gas (N, O), and atomic absorption spectroscopy on solutions (metallic impurities) [56].

10. Economic Aspects

The largest world reserves of rhenium are located in Chile which is today the world's largest producer. Other producers include Germany, CIS, Sweden, the United States, and Japan. In Germany, rhenium is obtained from molybdenum concentrates, spent catalysts, and rhenium-containing scrap, and processed to produce high-purity NH_4ReO_4, $HReO_4$, and Re metal powder or pellets [57]. The largest consumer of rhenium is the United States, which imported ca. 15 t of Re in 1990. This could increase to 20 t/a in the next five years. Rhenium is used for aircraft turbine blades (60 %), reforming catalysts (30 %), and other applications (10 %) [14].

11. Toxicology and Physiological Effects

No evidence exists that rhenium is an essential element for living organisms [58]. People who have worked over a long period of time in the extraction and production of rhenium metal and its most important compounds, perrhenic acid and ammonium perrhenate, have not shown any toxic effects. Toxicological investigations of rhenium and rhenium compounds are contradictory and do not enable any OECD guidelines to be issued [59].

Medical studies indicate that rhenium carboxylates have an antitumor effect [60]. Rhenium-188 and rhenium-186 are used in combination with monoclonal antibodies for the diagnosis and treatment of leukemia [61].

1. Introduction

The order Rodentia is the largest mammalian order with ca. 1500 species, although barely 100 of these are important as pests. Pest rodents belong mainly to the families Sciuridae (tree and ground squirrels), Cricetidae (voles, gerbils, and hamsters), and Muridae (rats and mice). Rodenticides are used in the control of all these animals and, occasionally, for the control of those belonging to the closely related order Lagomorpha (rabbits). Rodents are pests in both commensal and agricultural situations.

2. Commensal Rodents

Evidence of traps made to capture rodents in the early cultures of Mesopotamia and Egypt witness the long relationship between humans and these damaging animals. Three rodent species, the Norway rat (*Rattus norvegicus*), the ship rat (*Rattus rattus*), and the house mouse (*Mus musculus*), have their origins in Asia [1] but have spread to threaten the health and livelihoods of humans across the globe. The same species have even journeyed with humans to hundreds of oceanic islands and have done untold damage to their fragile ecosystems [2].

Diseases are transmitted from rodents to humans and domesticated animals, either directly by bites or exposure to infected feces and urine, or indirectly via a vector, usually an arthropod such as a fly or mosquito. The range of diseases is very large and their causative organisms include viruses, bacteria, protozoa, and helminths. Among the most important diseases carried by rodents and transmitted to humans are plague, leptospirosis, salmonellosis, typhus, leishmaniasis, trichinosis, schistosomiasis, and a number of hemorrhagic and relapsing fevers [3].

Almost all foodstuffs produced for consumption by humans and domestic animals are liable to damage by commensal rodents during processing and storage but financial loss is very difficult to define [4]. Norway rats and house mice prefer dry foods based on cereals, while ship rats prefer moist foods such as fruit.

The incisor teeth of Norway rats have a hardness of 5.5 on Moh's scale and, during gnawing, exert a pressure of up to 500 kg/cm^2 [5]. Armed with these formidable weapons, rodents damage a wide range of natural and man-made materials while gaining access to food and harborage and merely while relieving boredom. Of particular importance is the damage done to pipes, conduits, and cables, both because of the high cost of repair and the fires resulting from electrical short circuits.

An adult rat annually produces some 30 000 droppings and 8 L of urine. These, together with innumerable hairs, are shed indiscriminately and the cost of cleaning soiled commodities frequently far exceeds the value of foodstuffs actually consumed by rodents.

3. Rodents as Pests of Agriculture

Rodents are among the most damaging pests of growing crops. Cereals (e.g., rice, wheat, barley, and maize) and plantation crops (e.g.,

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_211

coconuts, oil palm, cocoa, and sugarcane) are highly vulnerable to attack. Some of the species responsible for these depredations are *Sigmodon hispidus* in Central and South America, *Arvicanthis niloticus* and *Praomys natalensis* in sub-Saharan Africa, *Bandicota bengalensis* in the Indian subcontinent, *Rattus tiomanicus* and *R. argentiventer* in south-east Asia, and *Rattus exulans* among the islands of the south Pacific [5]. In Europe, the main rodent pests of agriculture are voles, *Microtus agrestis*, *M. arvalis,* and *Arvicola terrestris* [6]. In the United States, a number of species of ground squirrels and voles are important pests of crops and rangelands.

4. Control of Rodents

Rodenticides are the mainstay of most rodent-control operations. They are principally applied in the form of poisoned baits, often based on cereals, and placed in areas where target rodents are active. In dry locations, such as cereal stores, rodenticides are occasionally presented in the form of liquids. A few compounds are also available as tracking dusts which are applied to surfaces over which the rodents pass. The contaminated rodents then ingest the poisoned dust during grooming.

The safe, effective application of rodenticides requires a degree of skill. Baits must be placed so that all rodents have access to them in sufficient quantity to acquire a lethal dose. Few of the compounds employed possess a substantial degree of specificity to rodents. It is therefore imperative to prevent the consumption of baits by nontargets by the exclusion of these animals from the baited area, by the careful placement of baits, or by the use of bait boxes.

Nonchemical methods of rodent control include the use of traps, the proofing of buildings against the ingress of rodents, modification of the environment to make it less conducive to rodent infestation (removal of food and harborage), and the use of predatory animals, such as cats and dogs. A number of devices are sold which emit ultrasound that is said to repel rodents. These, however, have been shown to be largely ineffective in most practical circumstances [7].

5. Rodenticides Used in Poisoned Baits

5.1. Acute and Subacute Rodenticides

Acute and subacute rodenticides induce rapid effects. The majority of *acute rodenticides* cause death, after the consumption of a lethal dose, within a few minutes to several hours. The fast onset of the symptoms of toxicosis has a drawback however. Rodents that consume only a sublethal amount of the poison associate the painful effects with the new food (i.e., the bait), and refuse to eat it again. These animals are said then to be bait shy. Bait shyness can be prevented, at least in part, by prebaiting. Here, unpoisoned bait of the type later to be used to carry the poison is first presented. The poison is only added when the rodents have overcome their initial suspicion of the novel food and are feeding freely on it. This technique maximizes the quantity of poison taken by rodents at their first feeding, thereby reducing the likelihood of sublethal exposure.

Subacute rodenticides also have relatively rapid effects, one of the most common being anorexia [8]. However, when a potentially lethal dose has been consumed, they cause death after ca. 1 – 3 days.

Zinc phosphide [*1314-84-7*], Zn_3P_2, trizinc diphosphide, M_r 258.06, $mp > 420\,°C$, is one of the most common acute rodenticides. It is generally available as a grey or black crystalline powder, 80 – 95 % purity, with a strong garlic odor. It is applied in baits at concentrations of 1 – 5 %, 2 % is most widely used. The acute oral LD_{50} for Norway rats is ca. 40 – 45 mg/kg [5]. Zinc phosphide is also highly toxic to a wide range of vertebrates (LD_{50} for pig, dog, cat, chicken, and mallard in the range 20 – 40 mg/kg) [9]. The mode of action is by the evolution of phosphine gas in the acid environment of the stomach. The gas enters the bloodstream, causing heart failure and damage to internal organs [10]. There is no specific antidote [9].

Red Squill is extracted from bulbs of the Mediterranean plant, *Urginea maritima.* The active substance, a cardiac and nerve glycoside, *scilliroside* [*507-60-8*], $C_{32}H_{44}O_{12}$, 3β(β-

D-glucopyranosyloxy-17β-(2-oxo-2*H*-pyran-5-yl)-14β-androst-4-ene-6β,8,14-triol 6-acetate, M_r 620.67, *mp* 168 – 170 °C, is slightly soluble in water and soluble in alcohols and glycol:

The rodent toxicity of crude extracts is very difficult to determine; an LD_{50} dose to Norway rats of 125 – 1500 mg/kg has been reported [9]. A purified extract is highly toxic to *Rattus norvegicus* (LD_{50} 0.4 – 2.6 mg/kg) and *Mus musculus* ($LD_{50} < 0.2$ mg/kg) [5]. Concentrations used in baits range from 0.015 to 0.05 %, although unpalatability [5] and bait shyness [11] have been reported. Symptoms of poisoning include hind limb paralysis, convulsions, emesis (except in rat), and excessive diuresis and diarrhea. Atropine sulfate is antidotal [9].

Trade Name. Stabilized extract, Silmurin (Sandoz).

Calciferol [*50-14-6*], vitamin D_2, ergocalciferol, $C_{28}H_{44}O$, (3β,5*Z*,7*E*,22*E*)-9,10-secoergosta-5,7,10(19),22-tetraen-3-ol, M_r 396.63, *mp* 115 – 118 °C [12]:

This naturally-occurring compound is used for rodent control both on its own and in combination with 0.025 % warfarin and 0.005 % difenacoum, although synergism is unproven [13]. It is stable in baits at a concentration of 0.1 % for at least 6 months, but after this time its efficiency may diminish [5]. The acute oral LD_{50} for rats and mice is 30 – 100 mg/kg. Smaller doses may be additive over a period of several days. However, there is some indication that sublethal doses cause anorexia and bait shyness [8]. Toxic doses in mammals stimulate the absorption of calcium in the intestines and the mobilization of skeletal calcium. This results in hypercalcemia, osteomalacia, and the calcification of soft tissues, particularly the major arteries and kidneys. Treatment of accidental poisoning is symptomatic with cortisone and sodium sulfate [5].

Cholecalciferol [*67-97-0*], vitamin D_3, has been introduced more recently as a rodenticide and has similar properties [5].

Trade Names. Sorexa-CD (ergocalciferol with difenacoum), Sorexa-CR (ergocalciferol with warfarin), both Sorex. Quintox (cholecalciferol), Bell Laboratories.

Bromethalin [*63333-35-7*], α,α,α-trifluoro-*N*-methyl-4,6-dinitro-*N*-(2,4,6-tribromophenyl)-*o*-toluidine, $C_{14}H_7Br_3F_3N_3O_4$, M_r 577.9, *mp* 150 – 151 °C. A pale yellow crystalline solid, insoluble in water, soluble in acetone, chloroform, and dichloromethane:

This compound has been known for some time to have rodenticidal properties [14] but has only recently been made available. The acute oral LD_{50} is in the range 2.0 – 8.1 mg/kg for rodents and 1.8 – 13.0 mg/kg for several nontarget species, such as dog, cat, rabbit, and chicken [15]. Bromethalin is used in baits at a concentration of 0.005 or 0.01 % and is effective against rodents resistant to anticoagulants. Anorexia occurs after an effective dose has been consumed. The mode of action is by uncoupling oxidative phosphorylation in cells of the central nervous system. Symptoms of poisoning include tremors, convulsions, prostration, and hind-limb paralysis. No specific antidote is available but a symptomatic treatment has been described [16].

Trade Names. Assault (Purina Mills), Vengeance (Dow-Elanco).

The following acute and subacute compounds are used for rodent control less frequently than those listed above, either because they are not widely available or because restrictions have been placed upon their use due to safety considerations [10, 17].

Sodium monofluoroacetate [*62-74-8*], $CH_2FCOONa$, $C_2H_2FNaO_2$, M_r 100, *mp* 200 °C, commonly known as Compound 1080, is highly toxic to rodents, having an LD_{50} to rats and mice in the range 0.1 – 17.0 mg/kg [9]. Baits contain 0.08 – 0.5 % of the active ingredient, which acts by blocking the tricarboxylic acid cycle, causing the accumulation of citric acid and leading to convulsions and respiratory or circulatory failure. The poison is nonspecific [5]. Because of its high toxicity, the lack of antidote, and its secondary hazard, the use of Compound 1080 is carefully regulated in many countries [9].

Fluoroacetamide [*640-19-7*], CH_2FCONH_2, C_2H_4FNO, M_r 77, *mp* 109 °C, a colorless, odorless, tasteless, white powder that is highly soluble in water [9]. Also known as Compound 1081, it is an analog of Compound 1080 and is similar to it. However, it is used at higher concentration because it is less potent. Used in bait at concentrations of 1 or 2 % it performed better than 0.25 % 1080 and is most often used in the control of rats in sewers and in other closed areas [5].

α-Chloralose [*15879-93-3*], (*R*)-1,2-*O*-(2,2,2-trichloroethylidene)-α-D-glucofuranose, $C_8H_{11}Cl_3O_6$, M_r 309.54, *mp* 187 °C, is a fast-acting narcotizing agent [9]. It slows several metabolic processes, causing hypothermia and eventual death. It is most effective against small rodents, such as mice, which have a high surface area-to-volume ratio, and in cool conditions. It is used in baits at concentrations of 2 – 8 % [5].

The use of thallium sulfate, pyriminyl (Vacor), silatrane, norbormide, and crimidine in rodent control has virtually ceased.

5.2. First-Generation Anticoagulants

The origin of first-generation anticoagulants lies in research conducted in the 1930s in the United States aimed at discovering the causative agent of a hemorrhagic disease of cattle. This was found to be dicoumarin, a contaminant isolated from spoiled sweet clover hay [18]. Further work focused on the potential of this compound and a series of synthetic derivatives in the treatment of human thrombosis. Warfarin, the most active of the series, was soon recognized as a promising therapeutic and rodenticide [19]. In the United Kingdom, dicoumarin itself was used in rodent control [20] until the superior potency of warfarin led to its replacement. The advantages of the anticoagulants over their fast-acting predecessors were quickly recognized and, by the early 1950s, their use dominated rodent control.

The benefits of anticoagulants are related to their chronic mode of action. They interrupt the vitamin K cycle by blocking the enzyme vitamin K epoxide reductase. Vitamin K is required in the production of several blood clotting factors. When recycling of vitamin K is blocked by the anticoagulant, dietary vitamin K is insufficient to maintain adequate clotting factor production. A few days after the ingestion of an effective dose, the factors circulating in the blood are depleted and clotting fails, leading to a fatal hemorrhage [5]. This delayed action means that rodents are unable to relate the symptoms of toxicosis to the anticoagulant that has caused it; therefore no bait shyness occurs. A further important advantage of these compounds is that vitamin K_1 is a specific antidote and, in cases of accidental poisoning, their chronic mode of action allows sufficient time for its administration.

During 1950 – 1970, a number of anticoagulant compounds were commercialized as rodenticides; all were either hydroxycoumarins or members of a related group, the indandiones. The compounds described in Section 5.2 are known as the first-generation anticoagulants. Although acute oral LD_{50} values are given for purposes of comparison, in practice it is unlikely that a lethal dose of any of these rodenticides would be consumed by rodents during a single episode of feeding on poisoned bait.

5.2.1. Hydroxycoumarins

Warfarin [*81-81-2*], 3-(α-acetonylbenzyl)-4-hydroxycoumarin, $C_{19}H_{16}O_4$, M_r 308.22, *mp*

159 – 162 °C, crystalline solid, insoluble in water, soluble in acetone [21]:

Although values for the acute oral LD_{50} of Norway rats vary between 1.5 and 323 mg/kg [9], the most reliable estimates place the figure between 10 and 20 mg/kg [22]; the strain and sex of the test animals and the carrier used in the administration affect the results. Warfarin is widely used for the control of Norway rats but other pest species, such as *R. rattus* and *M. musculus*, are less susceptible [23] and the compound is not much used in their control. A wide variety of formulations is available, including concentrates containing 0.5 – 1.0 % for bait preparation and use as tracking dusts and baits containing 0.025 – 0.05 % of the active ingredient [17]. Resistance to warfarin was first discovered in the United Kingdom in 1958 and is now established in Norway rat and house mouse populations throughout Europe and North America [23]. Mixtures of warfarin with both sulfaquinoxiline (Proline) and calciferol (Sorexa CR) have been used in proprietary products but the effectiveness of these additives has not been fully demonstrated.

Anticoagulants do not generally produce carcinogenic, teratogenic, or mutagenic effects but there is evidence that warfarin may adversely affect human fetal development [24].

Coumafuryl [*117-52-2*], 3-(α-acetonylfurfuryl)-4-hydroxycoumarin, $C_{17}H_{14}O_5$, M_r 298.28, *mp* 124 °C, is an early anticoagulant now rarely used in rodent control.

Coumachlor [*81-82-3*], 3-(α-acetonyl-4-chlorobenzyl)-4-hydroxycoumarin, $C_{19}H_{15}ClO_4$, M_r 342.79, *mp* 169 – 171 °C, colorless, crystalline solid [25]:

Few reliable data are available on the acute toxicity of coumachlor. The acute oral LD_{50} is given as 187 mg/kg for rats [26] and 900 – 1200 mg/kg for rats and mice [5]. However, the compound is more potent in small daily doses, with a chronic LD_{50} of only 0.1 – 1.0 mg kg^{-1} d^{-1} for 14 – 21 days [27]. The active ingredient is recommended in prepared baits at a concentration of 0.025 – 0.05 %. It is available as concentrates and tracking powders at both 0.5 and 1.0 % [17].

Trade Names. Ratilan, Tomorin (Ciba-Geigy).

Coumatetralyl [*5836-29-3*], 4-hydroxy-3-(1,2,3,4-tetrahydro-1-naphthyl)coumarin, $C_{19}H_{16}O_3$, M_r 292.34, *mp* 172 – 176 °C. Coumatetralyl is produced by the condensation of 4-hydroxycoumarin and 1,2,3,4-tetrahydro-1-naphthol [28]. It is an off-white crystalline powder that is practically odorless, tasteless, and virtually insoluble in water but soluble in many organic solvents:

First introduced in 1956, coumatetralyl is one of the most widely used first-generation anticoagulants. It is not, however, available in the United States. The acute oral LD_{50} for Norway rats is given as 16.6 mg/kg [29] but, as with many of these compounds, coumatetralyl is more potent when administered in consecutive daily doses (chronic LD_{50}, 0.3 mg kg^{-1} d^{-1} for 5 days) [26]. No satisfactory data are available on the acute oral toxicity of the compound to mice. However, a complete kill of mice was obtained in the laboratory following 21 days of feeding on coumatetralyl bait [30]. Proprietary baits generally carry 0.375 % coumatetralyl. Powder concentrates are available (strength 0.75 %) which are used for the preparation of poisoned baits and as a tracking dust [17].

Trade Name. Racumin (Bayer).

5.2.2. Indandiones

Diphacinone [*82-66-6*], 2-(diphenylacetyl)indan-1,3-dione, $C_{23}H_{16}O_3$, M_r 340.38, *mp* 145–147 °C, is a yellow powder that is soluble in many organic solvents [31]:

This compound is toxic to Norway rats. The acute oral LD_{50} is given as 2.3 mg/kg [26], 3.0 mg/kg [32], 17 mg/kg [33], and 23 mg/kg for females and 43 mg/kg for males [34]. It is, however, considerably less active against house mice, with acute oral LD_{50} values calculated at 141 mg/kg [29] and 340 mg/kg [32]. The compound is not widely used except for rat control in the United States and, as the sodium salt, for rodent control in China. It is available in a number of formulations, including 0.1–0.5 % powder concentrates; pelleted, meal, and wax block ready-to-use baits containing 0.005–0.05 % of the active ingredient; a 0.1 % water-soluble concentrate based on sugar; and tracking powders containing up to 2 % diphacinone [17]. Generally higher concentrations of the active material are used for mouse control than for rat control.

Trade Names. Diphacin, Ramik (Velsicol).

Chlorophacinone [*3691-35-8*], 2-[2-(4-chlorophenyl)-2-phenylacetyl]indan-1,3-dione, $C_{23}H_{15}ClO_3$, M_r 374.83, *mp* 140 °C. A yellow crystalline solid; sparingly soluble in water; soluble in acetone, ethanol, and ethyl acetate [35]:

This compound was introduced in 1961 and is now widely used in Europe, the United States, and elsewhere. The acute oral LD_{50} to *R. norvegicus* is 20.5 mg/kg [36]; the compound is used in baits against these animals at a concentration of 0.005–0.01 %. Bait containing 0.025 % chlorophacinone gave a complete kill of house mice after a 7-d feeding period but, in other tests, survivors were recorded following 10 and 21 days of feeding [5]. Chlorophacinone acts as an uncoupler of oxidative phosphorylation as well as an anticoagulant [26], which is unusual among this group of compounds.

Trade Names. Drat (Ciba-Geigy); Rozol (LiphaTech); Caid, Liphadione (Lipha).

Pindone [*83-26-1*], 2-pivaloylindan-1,3-dione, $C_{14}H_{14}O_3$, M_r 230.25, *mp* 108.5–110.5 °C, a yellow-brown crystalline solid, slightly soluble in water, soluble in organic solvents [37]:

First introduced as an insecticide, and only later commercialized for its rodenticidal properties [38], this compound is used mainly in the United States. The acute oral LD_{50} for Norway rats is given as 50 [29] and 280 mg/kg [39]. Baits containing 0.005–0.05 % have been used for the control of rats and mice. Pindone is similar to warfarin and its efficacy [5].

Trade Names. Pival, Pivalyn [sodium salt] (Motomoco).

5.2.3. Anticoagulant Resistance

The first substantiated case of warfarin resistance was recorded in Scotland in 1958 in Norway rats [40]. The phenomenon has now been widely recorded in Europe and North America in all three common commensal rodent species [5,20,23]. In the tropics, warfarin resistance has been found in *R. rattus* [41] and *R. tiomanicus* [42]. Warfarin-resistant rodent strains often possess cross resistance to many other first-generation compounds. More recently, resistance to difenacoum [43] and bromadiolone [44] has become evident in Europe.

Populations of Norway rats now exist in the United Kingdom and Denmark which are less susceptible to brodifacoum than normal. However, they remain sufficiently susceptible to be controlled with that compound [45]. The mechanism of anticoagulant resistance has been researched [46] but is still not completely understood.

5.3. Second-Generation Anticoagulants

The discovery of resistance to the first-generation anticoagulants threatened the gains made with the introduction of these highly successful compounds. In an attempt to overcome this problem, some chemists investigated alternative modes of action while others continued to work on the hydroxycoumarins. This latter line of research resulted in the discovery of a second generation of anticoagulant rodenticides [47]. These compounds are effective against rodents resistant to first-generation anticoagulants and are also more active against susceptible animals. Some are so active against most target species that, unlike the first-generation compounds, a lethal dose is ingested by rodents during a single episode of feeding on poisoned bait [29]. The second-generation anticoagulants retain all of the advantages of the earlier compounds. In particular, vitamin K_1 is antidotal, although the period required for its effective administration is prolonged [48]. This is because the second-generation compounds have long biological half-lifes [49–51]. The secondary hazard of these materials to predators has been reviewed [52].

Difenacoum [*56073-07-5*], 3-(3-biphenyl-4-yl-1,2,3,4-tetrahydro-1-naphthyl)-4-hydroxycoumarin, $C_{31}H_{24}O_3$, M_r 444.54, *mp* 215 – 217 °C. An off-white, odorless, crystalline solid synthesized by the condensation of 4-hydroxycoumarin and 3-biphenyl-4-yl-1,2,3,4-tetrahydro-1-naphthol; virtually insoluble in water; slightly soluble in benzene and alcohols; soluble in acetone, chloroform, and other chlorinated solvents [53]:

Appearing in 1974, difenacoum was the first of the new generation of anticoagulants to be commercialized for the control of rodents resistant to warfarin and related compounds [47]. LD_{50} values (acute oral) for warfarin-susceptible rodent strains are 1.8 mg/kg for Norway rats and 0.8 mg/kg for house mice. The equivalent figure for warfarin-resistant Norway rats is 3.4 mg/kg. There is also a degree of specificity. The compound is generally less toxic to nontarget animals than to targets (acute oral LD_{50} in mg/kg: pig > 50, dog 50, cat 100, chicken 50). A wide range of bait types containing 0.005 % difenacoum is available, including meals, broken and whole grains, pellets, and wax blocks. A 0.1 % contact dust is no longer widely used. Resistance to difenacoum was detected among a population of Norway rats in the United Kingdom in 1978 [54]. This remains a problem of local importance but relatively low resistance factors indicate that other behavioral factors also play a significant role [55]. Difenacoum resistance has also been recorded in other European countries [44].

Trade Names. Neosorexa (Sorex), Ratak (ICI).

Brodifacoum [*56073-10-0*], 3-[3-(4′-bromobiphenyl-4-yl)-1,2,3,4-tetrahydro-1-naphthyl]-4-hydroxycoumarin, $C_{31}H_{23}BrO_3$, M_r 523.44, *mp* 228 – 232 °C. An off-white/fawn, tasteless, and odorless powder; insoluble in water but soluble in certain organic solvents [53]:

Brodifacoum is the most potent second-generation compound. Rodents succumb after consuming bait as part of their food intake on only one occasion [26]. The acute oral LD_{50} values for brodifacoum against warfarin-susceptible rodents are: Norway rats 0.26 mg/kg, house mice 0.4 mg/kg, roof rats 0.73 mg/kg. The compound is, however, equally effective when employed to control rodent infestations resistant to warfarin and other anticoagulant rodenticides [43]. No difference is discernible between the acute and the cumulative, chronic toxicities of the material. Brodifacoum has been widely evaluated, both in the laboratory and in the field, against commensal and agricultural rodent pests [56]. Commercially available pellet, wax block, and cereal baits generally contain 0.005 % brodifacoum.

Trade Names. Brodifacoum (Sorex); Havoc, Klerat, Matikus, Talon (ICI).

Bromadiolone [*28772-56-7*], 3-[3-(4′-bromobiphenyl-4-yl)-3-hydroxy-1-phenylpropyl]-4-hydroxycoumarin, $C_{30}H_{23}BrO_4$, M_r 527.42, *mp* 200 – 210 °C. A yellowish powder insoluble in water; soluble in ethanol, ethyl acetate, and dimethylformamate:

This compound was patented in 1968 [57] and introduced to the market in 1976 [5]. The acute oral LD_{50} for Norway rats is 1.125 mg/kg and for house mice is 1.75 mg/kg [58]. It is generally used in baits against these species at a concentration of 0.005 % [59,60]. It is sufficiently potent to kill warfarin-suceptible Norway rats after one day of feeding but repeated feeding is required to kill resistant rats and house mice [5, 61]. Bromadiolone has a good palatability [5]. It is widely available in a variety of formulations, including cereal-based baits, oil-based concentrates, and powder concentrates, containing 0.1 – 0.5 % of the active ingredient, and tracking dusts at 0.1 – 2.0 % strength [17].

Trade Names. Bromone, Super-Caid (Lipha); Contrac, Maki (LiphaTech).

Flocoumafen [*90035-08-8*], 4-hydroxy-3-[1,2,3,4-tetrahydro-3-[4-(4-trifluoromethylbenzyloxy)phenyl]-1-naphthyl]coumarin, $C_{33}H_{25}F_3O_4$, M_r 542.6, *mp* 181 – 191 °C (*cis*), 163 – 166 °C (*trans*). An off-white powder insoluble in water; soluble in acetone, alcohols, chloroform, and dichloromethane [62]:

This compound was introduced in 1984 and is one of the most potent second-generation compounds. Acute oral LD_{50} (mg/kg) is 0.25 for Norway rats, 0.8 for house mice, and 0.18 for gerbils. It is less active against nontarget bird species (acute oral LD_{50} values: > 100 mg/kg for chicken, > 300 mg/kg for quail, and ca. 100 mg/kg for Mallard duck) but toxic to dogs (0.075 – 0.25 mg/kg) [63]. The main formulation available is a wax briquette containing 0.005 % flocoumafen; this is effective against rodent strains resistant to other anticoagulants and is used in a wide range of urban, industrial, and agricultural situations [64,65]. Pellet and grain baits are also produced.

Trade Name. Storm (Sorex, Shell).

Difethialone [*104653-34-1*], 3-[(1*RS*,3*RS*; 1*RS*,3*SR*)-3-(4′-bromobiphenyl-4-yl)-1,2,3,4-tetrahydro-1-naphthyl]-4-hydroxy-1-benzothiin-2-one, $C_{31}H_{23}BrO_2S$, M_r 539.2, *mp* 203 – 227 °C [66]:

Its structure differs from that of brodifacoum in the substitution of sulfur for the oxygen atom

in the hydroxycoumarin ring. LD_{50} values for warfarin-susceptible animals are 0.51 mg/kg for *R. norvegicus* and 0.48 mg/kg for *M. musculus* [50]. Satisfactory results have been obtained in laboratory tests with 0.0025 % difethialone baits against susceptible and warfarin-resistant rats and mice, both in Denmark [50] and France [67]. Exposure to the compound at this concentration for one day did not, however, give complete control [67]. Wheat baits carrying 0.0025 % of the active ingredient were effective for the control of *Arvicola terrestris* and *Pitymys duodecimcostatus* in the field [68]. Field trials against rats and mice have also been conducted successfully in the United States [69].

Trade Name. Frappe (Lipha).

6. Other Chemical Methods of Rodent Control

Fumigants are employed for rodent control when conventional methods are ineffective or impractical and when the structures and installations to be treated, such as ships, aircraft, and grain silos, can be sealed effectively or enclosed in a gastight membrane. They are also used applied directly to rodent burrows.

One of the most common fumigants is *phosphine* [*7803-51-2*] (PH_3), which is evolved when aluminum phosphide (AlP) formulations (trade names: Phostoxin, Degesch; Delicia Gastoxin, Ernst Freyberg; Celphos, Excel) are exposed to atmospheric or soil moisture. *Hydrogen cyanide* [*74-90-8*] (HCN) is similarly used, particularly for rabbit control in the United Kingdom, and is applied as sodium cyanide (NaCN) powder (trade name: Cymag, ICI). *Methyl bromide* [*74-83-9*] (CH_3Br) and *chloropicrin* [*76-06-2*] (CCl_3NO_2) are used less frequently. Fumigants are available formulated as powders, impregnated cardboard disks, pellets, and tablets, and as gases in steel cylinders. Great care is required in their use and, in many countries, only professionals are permitted to apply them.

Chemosterilants. Alternatives to compounds that cause the death of rodents have been sought for reasons of humaneness and concern for the environment. Chemosterilants cause infertility in animals that ingest an effective dose. Several of these compounds have been studied for their potential as rodent control agents [70–72]. α- *Chlorohydrin* [*96-24-2*] (3-chloro-1,2-propanediol) is one of the few to have been commercialized [73]. It sterilizes male Norway rats at a dose of 90 – 100 mg/kg (acute oral LD_{50} is 150 – 160 mg/kg) and is available as a 1 % ready-to-use bait and as 20 % concentrate (trade name: Epibloc, Gametrics). Chemosterilants are not widely used in pest control because their effects are often transient and the presence of rodents, sterile or not, is considered undesirable.

Repellants. Many substances suppress rodent consumption of foods treated with them. For example, certain rodenticides are unpalatable to rodents when applied at concentrations higher than those normally used. It is surprising, therefore, that a fully reliable chemical rodent repellant has not been discovered. *Thiram*, *tetramethylthiuram disulfide* [*137-26-8*] [74], and *Rotran* [*3304-97-0*], a tertiary butylsulfenyldimethyldithiocarbamate [75], have been used as rodent repellants. A series of naturally-occurring phenolic compounds has promising properties [76].

A useful advance towards the increased safety of rodenticidal preparations is the introduction of the human taste deterrent *denatonium benzoate* [*3734-33-6*], *N*-[2-[(2,6-dimethylphenyl)amino]-2-oxoethyl]-*N,N*-diethylbenzenemethanaminium benzoate, $C_{28}H_{34}N_2O_3$, M_r 446.5, *mp* 163 – 170 °C. This compound is highly repellant to humans when included in rodenticidal baits at a strength of 0.001 % but does not deter their consumption by rodents [77]. Incorporation of this compound is unlikely to decrease the frequency of accidental exposure of humans to baits. It will, however, reduce the quantity of accidentally consumed bait and, thereby, the clinical severity of these incidents.

3. History 2
4. Nomenclature 3
5. References 4

1. Definition

The terms *rubber* and *elastomer* are often used incorrectly. DIN 53 501 and DIN 7 724 give exact definitions, differentiate between these two terms, and also define the term *vulcanization*. Vulcanization is also defined in ISO 1382 no. 1003. In these standards, high molar mass polymeric materials are classified according to the temperature dependence of their mechanical properties.

Rubber (raw rubber) is a non-cross-linked, but cross-linkable (vulcanizable) polymer with rubber-elastic properties at room temperature.

At higher temperature or under the influence of deforming forces, raw rubber exhibits increasing viscous flow, so that it can be molded under suitable conditions. Raw rubber is a starting material for the production of elastomers.

Elastomers are polymeric materials that are cross-linked (vulcanized) up to their decomposition points. They are hard and glassy at low temperature and do not exhibit viscous flow even at high temperature. They have rubber-elastic properties, particularly from room temperature up to their decomposition point.

Rubber-elastic behavior is characterized by a relatively low shear modulus with a rather slight temperature dependence.

Elastomers exhibit a glass transition temperature of $< 0\,°C$ in the torsional vibration test according to DIN 53 520. Their shear moduli lie in the range $0.1 - 1000\,N/mm^2$ and remain almost constant between ca. 20 °C and the decomposition temperature.

Vulcanization is a process in which rubber, through a change in its chemical structure (for example, cross-linking), is converted to a condition in which the elastic properties are conferred or re-established or improved or extended over a greater range of temperatures. In some cases, the process is carried to a point where the substances become rigid (ISO 1382 no. 1003).

2. Rubber Elasticity

The difference between the mechanical properties of elastomers and those of other materials, such as metals and thermoplastics, is the result of different energy storage mechanisms. Metals, for example, alter their energy content on deformation by changing the distances between atoms; thermoplastics do so by deformation of the valence angles of the molecules. Therefore, metals and thermoplastics cool on elongation, and the tension due to deformation is lowered on heating.

Rubber elasticity is caused by entropy changes. An elastomer that is cross-linked by chemical or van der Waals bonds is forced into a more highly ordered conformation under extension. This leads to a decrease in entropy. When the load is removed the polymer molecules return to their original position with an increase in entropy. This is the reason elastomers warm up when elongated and the tension increases on heating. Prerequisites for rubber-elastic properties are

1) Sufficient cross-linking (i.e., polymer chains may not slide away from each other completely or undergo viscous flow)
2) Sufficiently high mobility of the longer chain segments (this is the case only at 20 – 70 °C above the glass transition temperature)

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_221

3) A highly amorphous state because crystallization limits chain mobility.

3. History

The old term *caoutchouc* was taken from the word *Caao-Chu* meaning "weeping tree." Many useful objects were made from the milk of the weeping tree by the indigenous people of the Amazon region long before white men discovered South America. When this tree, belonging to the spurge family, became known in Europe, botanists gave it the name *Hevea brasiliensis*. The milk produced is an aqueous emulsion or dispersion of oils, fats, waxes, resins, starch, proteins, and the main component, polyisoprene, which contains a high proportion of double bonds with the *cis* configuration. The milk occurs in more than a thousand species of plants, all of which are dicotyledonous angiosperms.

In 1495, Christopher Columbus, on his second journey to the New World, was the first white man to observe Indians in Haiti playing with an elastic ball. A quarter of a century later, the Spanish adventurer Fernando Cortez brought knowledge of the new, elastic, hitherto unknown material back to Europe.

More than 200 years later, in 1751, the people of Europe were reminded of the existence of natural rubber in an article by the French scientists C. M. de la Condamine and C. F. Fresneau. The first molded articles (rubber tubes and shoes) were produced in 1765, after P. I. Macquer and L. A. M. Hérrissant, succeeded in dissolving natural rubber and achieving the same properties, after evaporation of the solvent (ether and turpentine), that the rubber had before dissolution. In 1770 the Englishman J. Priestley reported the discovery of the erasing effect of natural rubber by the mechanic Edward Nairne. In 1826, M. Faraday discovered that the basic building block of natural rubber molecules was a hydrocarbon with five carbon atoms. This compound was later named isoprene. At this time the world rubber consumption was ca. 150 t. The discovery of hot vulcanization by Charles Goodyear in 1839 led the way to many new applications.

Practical uses were made possible only by the further development of vulcanization by Thomas Hancock in 1843, after which rapid development ensued. In 1845, R. W. Thomson applied for a patent for the first air-filled tires at the London patent office. By 1856, worldwide consumption of rubber had reached 7000 t. Because of the sharply increasing need for rubber arising from the growing number of applications and the Brazilian rubber monopoly, rubber was for a time more expensive than silver.

In 1873 the Englishman Cross succeeded in a first attempt to smuggle 3000 caoutchouc seeds and plants out of Brazil. Despite the most careful treatment, the seeds did not germinate. Three years later, Henry Wickham brought 70 000 seeds to England legally, and these germinated in Kew Gardens [14].

From the original 70 000 seeds, 2600 rubber seedlings were shipped to India, Ceylon, Singapore, and Malaysia. Of these, 1800 grew and ca. 5 – 7 became ready to tap. The latter were the ancestors of all the rubber trees in Southeast Asia.

In 1887 the Frenchman G. Bouchardat was the first to succeed in producing *synthetic rubber* by polymerization of isoprene obtained by dry distillation of rubber. The polymerization was performed over several months. In the years that followed , rapid development in tire production occurred after the manufacture of the first tires by Macintosh, Dunlop, Michelin, and Goodrich.

In 1900 the Russian chemist J. Kondakov succeeded in polymerizing the more readily accessible dimethylbutadiene by lengthy heat treatment to give methyl rubber. This was the first completely synthetic rubber with a composition that differed from natural rubber.

The first usable synthetic rubber (polyisoprene) was produced by the German chemist Fritz Hoffmann in 1909. In 1910 the German researcher C. D. Harries and, independently, the English chemists F. E. Matthews and E. Strange created the basis for large-scale industrial synthetic rubber production through the discovery that the polymerization of dienes can be initiated by alkali, particularly sodium. Because of the increasing use of automobiles at the beginning of the 20th century the price of rubber rose to 14 €/kg. At this time, world rubber consumption was 100 000 t.

The first completely synthetic isoprene rubber tires were produced at the Farbenfabriken

Bayer. With these tires, CARL DUISBERG drove from Leverkusen to Freiburg im Breisgau without a puncture. Impressed by this performance, Kaiser Wilhelm II had all his cars fitted with these tires.

The first industrial production of methyl rubber took place at Bayer, Leverkusen, between 1915 and 1918 because Germany was cut off from natural rubber supplies during World War I. In total, 2500 t was produced. At the beginning of the 1920s a synthetic rubber with the name Buna (butadiene with natrium, i.e., sodium catalysis) was produced. This name is still used today for many types of synthetic rubber.

In 1929, W. BOCK developed the basis for the general economic exploitation of synthetic rubber – the emulsion polymerization of butadiene and styrene. Styrene – butadiene rubber (SBR) is still the most widely used synthetic rubber.

At the beginning of the 1930s the first oil resistant rubber, nitrile rubber (NBR) was discovered by TSCHUNKUR, shortly afterwards, W. H. CAROTHERS developed polychloroprene, which is resistant to ozone and weathering.

Other important dates in the history of rubber are

1937	polyurethane rubber developed by OTTO BAYER
1942	silicone rubber
1943	butyl rubber
1948	fluororubber
1949	acrylate rubber
1953	chlorosulfonated polyethylene
1959	ethylene – propylene rubber developed by G. NATTA and G. CRESBY, based on Ziegler – Natta catalysts
1961	ethylene – vinyl acetate rubber
1962	styrene – butadiene – styrene (SBS) block copolymers, which led to the first thermoplastic elastomers
1965	epichlorohydrin rubber
1970	thermoplastic polyurethane rubber
1973	thermoplastic copolyesters
1975	polynorbornene rubber and hydrogenated nitrile rubber
1978	ethylene – acrylate rubber
1979	thermoplastic elastomers based on cross-linked ethylene – propylene rubbers
1981	polytetrafluoroethylene – polyolefin blends
1985	amorphous thermoplastic chloropolyolefin elastomers and introduction of a very highly resistant fluoroalkoxyphosphazene rubber
1989	ethylene – chlorosulfonated – polyethylene copolymers

In 1996 worldwide consumption of rubber was 15.6×10^6 t, of which 63 % was synthetic rubber. Until 2000 an average annual growth rate of the total rubber market of 2.7 % is expected.

The development of ever more specialized types of rubber, principally since 1965, shows that products require custom tailoring of properties for certain areas of application. Otherwise the ever higher requirements of vulcanized products could no longer be fulfilled.

With the continued development of catalyst systems and process technology new synthetic rubbers have been added so that today there are more than 25 different types of synthetic rubber. Most of these, like natural rubber, are hydrocarbons but with varying degrees of saturation of the carbon polymer chain and differing polarities as a result of the substituent side groups. It is these factors which are largely responsible for resistance to the destructive effects of outside influences such as heat, oxygen, ozone and chemicals and to swelling caused by mineral oils and fuels. Exceptions are epichlorohydrin rubber with carbon and oxygen in the polymer chain, polysulfides based upon carbon and sulfur and inorganic rubbers such as silicone with a silicon – oxygen polymer backbone or polyphosphazene with phosphorus and nitrogen in the main chain. These latter two materials are characterized by exceptional resistance to heat.

Each type of synthetic rubber exists as a family of products with a range of grades to suit different processing and end use requirements. The *Synthetic Rubber Manual* of the International Institute of Synthetic Rubber Producers now lists several thousand products from manufacturers around the globe.

Despite all the progress in the development of new synthetic rubbers, the importance of natural rubber has not diminished. In terms of quantity produced it is still the most important rubber, and in its mechanical properties it has so far not been surpassed by any synthetic rubber.

4. Nomenclature

Only in a very few cases are various types of rubber known by their IUPAC names. The ASTM D 1418-90 names and abbreviations are the most widely used. The most important abbreviations are given in Rubber, 3. Synthetic, Chap. 1.2.

1. Introduction

Many plants contain a milky juice – an aqueous emulsion or dispersion of oils, fats, waxes, resins, starch, and proteins. More than 1000 plant species contain aqueous dispersions of rubber – or, more precisely, of 1,4-polyisoprene with a high content of *cis* double bonds.

Rubber occurs only in seed-bearing plants (spermatophytes),which are also dicotyledonous angiosperms. Within one genus the phylogenetically younger forms always produce more rubber than the older ones. Thus, rubber formation appears to be the result of more recent evolution.

With regard to economic importance, rubber plants can be divided into three groups:

1) Plants from which rubber is currently extracted: *Hevea brasiliensis*, which provides more than 99 % of the rubber from natural sources.
2) Plants that were used in the past or are being investigated for future use: about 50 species, in particular, *Ficus elastica* (rubber plant), *Funtumia castilla*, kok-saghyz (*Taraxacum),* guayule (*Parthenium argentatum*), cassava, and tapioca bush. The guayule shrub is in a special situation. Its economic exploitation is constantly being reinvestigated in the United States and Mexico.
3) Rubber plants whose exploitation has not yet been investigated: ca. 1000 species.

All trees and bushes have a layered structure. From inside out are the heartwood, the sapwood, the cambium, the phloem, and the bark. In the cambium, which consists of only one layer of cells, new cells are continuously formed during the growth period. Those to the inside become wood and those to the outside become phloem. Latex is produced between the cambium and the phloem. Latex can be formed in three types of location: milk vessels, milk tubes, or milk cells.

Milk vessels consist of an associated system of tubes between the bark and the cambium, to which new cells are being joined continuously. However, the whole plant does not have a single

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_225

milk vessel system throughout, but rather many individual ones. Each system extends from the roots via the trunk to the twigs but is not connected to the other systems. Examples of plants with milk vessel systems are *Hevea* and cassava.

Milk tubes consist of a branched tube system permeating the entire plant. They are found, for example, in poinsettias or crown-of-thorns (*Euphorbia spendens*).

Milk cells are individual, isolated, elongated cells. Latex exudes only from cut cells, and tapping is not possible. Such cells are present in lettuce, chamomile, and salsify.

Hevea brasiliensis. The habitat of the rubber tree is the Amazon rain forest. Today, plantations of *Hevea brasiliensis* are also found in Southeast Asia, principally in Thailand, Indonesia, and Malaysia. When growing in the wild these trees live for more than 100 years and grow to more than 40 m high; on plantations their height is kept to less than 20 m. *Hevea brasiliensis* requires temperatures of 25 – 30 °C, at least 2000 mm of rainfall per year, and high atmospheric humidity. For this reason it grows only between 15° North and 15° South.

More than 99 % of natural rubber currently comes from *Hevea brasiliensis*. After an initial growth period of 5 – 7 years, a tree gives latex for ca. 25 – 30 years. *Hevea brasiliensis* is very suitable for rubber extraction for the following reasons:

1) It can be tapped because of its milk vessels.
2) It does not form resins on tapping.
3) Polyisoprene with almost 100 % *cis* double bonds is produced.
4) It tolerates tapping over a period of many years very well.

In the second half of the 19th century the conditions for a rapid expansion of the rubber industry were created by the discovery of vulcanization. The development was impeded only by the difficulties in extracting natural rubber in sufficient quantities. The only source was Brazil, where wild rubber was extracted by inadequate and dangerous methods. In tapping expeditions to the often widely scattered trees, deep cuts were made in the trees with axes, which destroyed the milk tube systems. This careless harvesting resulted in rapid exhaustion of the sources, so the tappers had to penetrate ever further into the jungle, with the increasing danger of disease and attacks by natives. For these reasons the price of rubber was higher than the price of silver for a time.

On the initiative of Sir Clements Markhem the India Office and the London Bontanical Garden decided to cultivate *Hevea brasiliensis*. They commissioned Henry Wickam to procure the seeds of the plant. In 1874 he collected 70 000 seeds and shipped them to England for a fee of £70. Contrary to all claims, the export of *Hevea* seeds was legal. However, a problem arose because Brazilian customs operated very slowly and *Hevea* seeds were capable of germinating only for a relatively short period and therefore had to be brought quickly to Kew Gardens near London. Wickam solved the problem with the aid of the British consul in Para and several £1 notes. Of the 70 000 seeds, about 2600 germinated and about 1800 grew. Most of them were shipped to India and Ceylon, where they perished because of the unsuitable climate. A few plants (50 in 1876 and 22 in 1877) were taken to Malaysia and Singapore, and of those, about 5 – 7 could later be tapped. They formed the basis for the current world natural rubber production.

Today's *Hevea* plantations are predominantly in Southeast Asia: Malaysia (24 % of world production), Indonesia (24 %), and Thailand (25 %); some can also be found in Africa (6 %). In Brazil, rubber trees could not be planted for a long time because of a widespread fungal disease *Dothidella ulei*. In Africa and Asia this disease has thus far not appeared because the climate is slightly different from that in Brazil. An attempt is now being made to solve this problem by cross-breeding with resistant *Hevea* species, so that *Hevea brasiliensis* can again be planted in Brazil.

2. Rubber Extraction

Latex is extracted from *Hevea brasiliensis* by tapping, which involves making a downward-slanting cut in the bark of the tree with a knife around half the circumference of the trunk at an angle of 30 – 35°. The inner cambium must not be damaged in the process because, otherwise, irregular reformation of the bark would lead to difficulties with the next tapping cut. In 2 – 5 h,

ca. 50 cm^3 of latex exudes from the cut (ca. 15 g of rubber). It is collected in a vessel fixed at the lower end of the cut. Later the cut is closed by the drying latex. After two days, this rubber film is removed and tapping is continued.

Although this is the most common tapping method, others also are used (e.g., instead of being cut, the bark is pierced with sharp needles).

Ca. 2 kg of rubber is extracted per tree per year. This corresponds to 1000 kg per hectare per year at 500 trees per hectare. Originally, the annual yield of a plantation was 350 kg per hectare; today, it is 600 – 700 kg per hectare per year, if the entire planted area is considered, including trees that are not ready for tapping, those that are too old, and newly planted areas. Targeted cultivation has enabled average annual yields of more than 1500 kg per hectare to be achieved on large plantations, particularly in Malaysia. On experimental plantations, yields have even been increased to 2500 kg per hectare.

Ca. 80 % of the production originates from smallholdings. The typical smallholder, with his family, works 1.25 hectares with about 625 *Hevea* trees. With 288 harvesting days, he has to tap 90 000 times per year in a 2-day cycle. He can harvest 625 kg of natural rubber per year from the lower-yield trees (500 kg per hectare). At \$ 0.27 – 0.33/kg, the smallholder earns \$ 209 per year. From this he has to feed, on average, 3.2 people, and he is at the minimum subsistence level for a family of three.

In summarizing the problems of natural rubber extraction from *Hevea* (suitable climate; large area required; abundant, cheap work force needed), it becomes clear that natural rubber plantations are uneconomical in highly developed countries. In the United States and Mexico, attempts are being being made to counteract these problems by extraction of natural rubber from guayule. In guayule the rubber latex occurs in individual milk cells and therefore cannot be obtained by tapping. In the autumn harvest, shrubs are pulled up by machine and ground; the rubber is extracted with solvents and separated from resins. The rubber is then processed further in a process that can be automated extensively. Guayule grows in arid deserts that could otherwise not be used, so the large area required does not play an inhibitory role.

3. Composition of Natural Rubber Latex

Natural rubber latex is essentially a dispersion of *cis*-1,4-polyisoprene in water. The average particle size is between 0.15 and 3.0 µm. The particle-size distribution is very broad. The aqueous dispersion contains between 30 and 38 % solid material, depending on the time of the year and the age of the tree. Other components of the latex are 1 – 2 % proteins and phosphoproteins, 2 % resins, 1 % fatty acids, 1 % carbohydrates, and ca. 0.5 % inorganic salts. The rubber particles are surrounded by protein anions and are thus effectively negatively charged, which hinders coagulation of the latex. These proteins are decomposed rapidly by bacteria and enzymes when exposed to air, and the rubber then partially coagulates. In addition, in the presence of air, cross-linking of the rubber occurs within the latex particles, with gel formation and subsequent degradation of the polymer chains.

4. Biosynthesis of Natural Rubber [16–18]

In the plant, natural rubber is not formed by polymerization of unsaturated monomers (e.g., isoprene); instead, a polycondensation occurs, starting from a basic unit of five carbon atoms, isopentenyl pyrophosphate.

If the formation of the basic building block is considered in a highly simplified form (see Fig. 1), a molecule with six carbon atoms (β-hydroxy-β-methylglutaric acid) is built up from three acetyl groups. β-Hydroxy-β-methylglutaric acid is then reduced to mevalonic acid. The latter eliminates CO_2 and water to give isopentenyl alcohol, or more precisely its ester with pyrophosphoric acid. In the second stage of polycondensation, isopentenyl pyrophosphate is condensed with one molecule of dimethylallyl pyrophosphate, which is formed from isopentenyl pyrophosphate by isomerization. In this way, geranyl pyrophosphate is produced, which reacts with another molecule of isopentenyl pyrophosphate to give farnesyl pyrophosphate. The condensation is repeated until the final molecular mass of natural rubber is reached. The entire process is controlled enzymatically.

Figure 1. Simplified scheme showing synthesis of natural rubber.

Why the plant forms latex is thus far not clear: the milky juice or the rubber precipitated from it does not appear to have any protective function in the plant. Two theories are currently being discussed:

1) The rubber constitutes an energy reserve that the plant can degrade when energy is needed.
2) The rubber is a product of excretion, with which the plant can render toxic metabolites harmless.

Both theories have been supported by a number of investigations, but refuted by an equal number. Possibly, no single reason exists for latex formation.

5. Commercial Extraction of Natural Latex [19–24]

When latex was first extracted, the problem was to stabilize it toward enzymatic and oxidative attack by bacteria. Today, an aqueous ammoniacal solution (ca. 0.7 %) is generally used to counteract degradation. In some cases, ammonia is used in combination with phenol or alkali phenolates.

Natural latex is concentrated to lower the transportation costs. Three processes are essentially available for this:

1) Centrifugation
2) Creaming
3) Evaporation

Electrodecantation is also sometimes used.

Centrifugation of the fresh latex allows extensive separation of the lighter disperse rubber phase from the aqueous serum. About 80 % of the rubber phase remains in the concentrate, and the solid content is up to 60 wt %. Most of the other latex components and rubber particles with smaller diameters remain in the serum. Thus the concentrated latex has a higher average particle size than the original latex. The process is continuous and therefore very economical, and is the most commonly used method of concentration.

Creaming Method. In the creaming method, 0.25 wt % ammonium alginate and 0.5 wt % ammonium oleate are added to the latex. In the course of several days the latex separates into two layers, of which the upper has a rubber content of ca. 60 %. After separation of the serum and renewed creaming, a concentration of 65 – 68 % solid materials is achieved.

Evaporation. Latices produced by evaporation have a very high solid material content (up to 75 wt %) because the very small particles are still present, unlike centrifuged latex. They also differ from the latex obtained by the other processes in that they contain all the water-soluble solids. Evaporation is the most expensive and least used process.

Uses. When the transportation problem was solved by stabilization, natural latex could be used worldwide and became more and more competitive with synthetically produced latex. The areas of use of natural rubber latex are those in which high toughness, elongation, and resistance to tear propagation in the vulcanizate and the raw material are required. Natural latex is as yet unsurpassed in the sum of these properties. The main areas of use are in diving gear, rubber thread, adhesives, and foam linings for carpets.

6. Production of Natural Rubber

Most of the natural rubber latex is further processed to solid rubber; in this case, no concentration of the latex is necessary. The rubber can be obtained by evaporation, spray drying, or the most important process, coagulation and subsequent drying.

6.1. Extraction by Evaporation of Water (Evaporation, Spray Drying)

The tappers in the Brazilian jungle extract the rubber from the milky juice. The latex is poured onto an oarlike piece of wood covered with clay and dried by rotating the wood over a smoky fire. Addition of urikuri nuts to the firewood gives the smoke a high phenolic content. The process is stopped when a large lump has been produced. This highly smoked wild rubber is called hard-cure fine para. It is qualitatively a very high-value natural rubber, because in this processing method the most valuable parts of the latex solidify while those of low value drop off. The preserving effect of the phenol- containing smoke is so good that the rubber lumps can be stored for years without mold formation.

In *spray drying* the latex is poured onto a rapidly rotating disk atomizer. From this it falls in finely divided form into a drying tower, into which hot air is blown in countercurrent. The dry material is obtained in the form of small flakes that are later pressed together to form blocks. This type of rubber is called sprayed rubber. It contains all the solid components of the natural rubber latex and has very good mechanical properties. Unlike coagulated rubber it is very tough and difficult to process.

6.2. Coagulation

On a plantation the rubber is separated from the latex by coagulation. Acids, such as formic or acetic acid, or salts, such as sodium silicofluoride, are used as precipitating agents. The latex is first diluted to a solid material content of 15 – 20 % and coagulated at pH 5.1 – 4.8 (isoelectric point). The coagulate must be processed further immediately; otherwise, it will be attacked by bacteria. Most of the water-soluble substances in the natural rubber latex remain in the serum.

Two main processes are used to *stabilize* the raw rubber: the smoked-sheet and the crêpe rubber processes.

Smoked sheets still contain a large proportion of other substances present in the latex. In the production of smoked sheets the diluted latex is treated with 1 part of 0.5 % formic acid to 10 parts of latex in long, rectangular vats with constant stirring. After skimming, aluminum plates are placed upright in the vats about 4 cm apart. The next day the coagulated rubber formed between the plates is removed. These soft, completely homogeneous rubber plates are rolled out with a hand roller and processed further on a sheet mangle. The latter consists of five pairs of press rollers arranged in series.

The resulting sheets of 3 – 4-mm thickness are hung in a smokehouse and treated with phenol- containing smoke, produced by burning fresh wood and nutshells, to protect the rubber against oxidation and mold formation. After the smoking process the temperature is raised to 60 °C and the sheets are dried for two to three days.

The standard grades of *ribbed smoked sheets* are rated in terms or purity and quality from 1 (very good) to 5 (poor quality). In addition, an unsmoked grade *air-dried sheets*, is an odorless, top-quality, light-brown product of high purity, whose vulcanizate has very good mechanical properties. Air-dried sheets are produced by grinding the moist coagulate, extruding it, and after renewed grinding, washing it in washing mills. The rubber is then air-dried and molded into plates several millimeters thick.

Crêpe Grades. The crêpe grades are freed extensively from nonrubber components by washing in washing mills. The quantity of coagulating agent is calculated so that, after a few hours, the 15 – 20 % latex yields a soft, cohesive coagulate from which a clear serum gradually separates. To remove the acidic residues and most of the nonrubber components the coagulate is washed under friction in ribbed mills with powerful water scrubbing. The process is repeated with increasingly closely spaced rollers having increasingly fine ribbing, until thin crêpe-like sheets are obtained. These are dried either

for 10 to 12 days in air or with a vacuum dryer at 70 °C for 2 h. With the vacuum dryer the product must be cooled very quickly to avoid surface oxidation. The crêpe grades all have a brownish color and are stabilized with 0.5–0.75 wt % sodium hydrogensulfide before coagulation. Here, the grades also differ according to color, purity, and strength of the sheet.

The *secondary grades* play an additional, economically important role. These generally consist of rubber from small plantations, which has been processed in very different ways and from which a crêpe is produced by mixing and milling them together. This crêpe is sold as *remilled crêpe*. *Flat bark crêpe* is produced from the dried rubber films that form where the tree has been tapped and from waste material.

Special Grades. Two special grades exist: *initial concentration rubber* [25], which is coagulated from undiluted latex, and *Hevea crumb* [26]. The latter is a crumblike rubber that gives a moist coagulate on addition of an incompatible oil, such as 0.7 % castor oil. The coagulate is crumbled by passage through conventional crêpe rollers. Approximately 0.4 % of the castor oil remains in the rubber, but it does not affect the properties significantly. Because of the large surface area of the crumb the rubber can be purified readily by washing with water and is dried in a deep-bed dryer with air circulation at 80–100 °C in 3 to 4 h. The *Hevea* crumb is molded into compact lumps and classified according to the standard malaysian rubber scheme (see Section 7.2).

Superior-Processing Rubber. Another form of natural rubber is superior-processing rubber (SP rubber, see Section 10.7) [27–34]. It is produced by coagulation of a mixture of normal and vulcanized latex. The advantages of SP rubber are better processing properties, particularly in injection molding and calendering.

There is also *premasticated natural rubber*, whose molecular mass is degraded significantly through the addition of chemicals, which is very easy to process.

7. Classification

Even with strict working instructions for coagulation and processing, the standard grades, such as crêpe and smoked-sheet rubber, produced from plantations differ in their processibility and rate of vulcanization. Constant quality control is therefore necessary, and guidelines for the classification of natural rubber were worked out at the suggestion of the French Rubber Institute in Indochina in 1949.

Natural rubber that has been classified according to these guidelines is known as technically classified (TC) rubber. This classification was further improved by Malaysia, and the so-called standard malaysian rubber (SMR) scheme was introduced.

7.1. Technically Classified (TC) Rubber [35]

Natural rubber is classified according to its Mooney viscosity and the tensile modulus of a standard vulcanizate. A blue circle on a lump means, for example, that the natural rubber shows average plasticity during processing and has a high vulcanization rate.

Since 1953 the Mooney viscosity has no longer been quoted by some plantations, because it gives no indication of the processing behavior of the natural rubber. However, the tensile strength of test vulcanizates has proved to be important for calibration of the vulcameter (→ Rubber, 6. Testing).

7.2. Standard Malaysian Rubber (SMR) [36–42]

The quality features of SMR are laid down in a technical specification. They are

1) Dirt content
2) Ash content
3) Copper, manganese, and nitrogen content
4) Content of volatile components, and
5) Plasticity retention index (PRI)

In determination of the *PRI*, rubber is heated to 140 °C for 30 min and the plasticity is measured before and after. The ratio of the former to

the latter number multiplied by 100 is the PRI. The PRI characterizes the degradation behavior of natural rubber. It gives an indication of the expected aging properties and of the mixing viscosity, which is in turn related to tensile strength, dynamic properties such as rebound resilience, and hysteresis. At the end of 1970 the so- called MOD value was introduced, which is also a measure of vulcanization behavior.

There are also constant-viscosity (CV) and low-viscosity (LV) grades. *Constant viscosity* is achieved by saturating the aldehyde groups, which are formed in the oxidation of natural rubber, with hydroxylamine, thus hindering hardening. Naphthenic oil is added to the *low-viscosity* grades to decrease the viscosity.

Another grade is *dynat rubber.* This is an SMR grade processed by air drying.

Since its introduction in 1965, much success has been achieved in the standardization of natural rubber by use of the classification scheme. The proportion of natural rubber classified according to the Malaysian scheme was more than 40 % in 1990.

7.3. Standardized Indonesian Rubber (SIR)

The SIR classification is not widely used and corresponds generally to the SMR classification.

8. Physical and Technological Properties of Solid Rubber

At 20 °C the density of natural rubber is 0.906 – 0.916 g/cm^3, the specific heat is 1.905 kJ kg^{-1} K^{-1}, and the refractive index ca. 1.5191. The heat of combustion is − 45.2 kJ/kg. The UV absorption of thin rubber films begins at 310 nm; complete absorption occurs below 225 nm.

Electrical properties are affected mainly by water-soluble nonrubber components. The electrical conductance is 2×10^{-15} to 1×10^{-13} S/m.

Natural rubber is generally processed after mastication, which gives it excellent processing properties. These include rapid sheet formation in open roll mills, high toughness of the unvulcanized mixture (green strength), and high building tack. The tack and green strength are very important properties for the production of composites, in which various layers must be welded together as in tires or pneumatic springs. Natural rubber also exhibits excellent behavior on extrusion and calendering. Another positive feature is the high vulcanization rate. On *cooling and subsequent tempering* at ca. 10 to −35 °C, natural rubber becomes opaque and inelastic. This effect is caused by partial crystallization.

On *elongation* to more than 100 % the forced alignment of the chains also induces crystallization (elongation crystallization), which can be detected by the appearance of diffraction patterns in X-ray diagrams. The elongation crystallization leads to a strengthening effect and a higher tensile strength in the direction of elongation (anisotropy of mechanical properties). The result is a high green strength of unvulcanized and vulcanized mixtures. Crystallites formed at greater elongation do not melt when the load is removed. Thus they hinder, for example, propagation of an edge tear. In an intermittent stress – strain experiment the elongation crystallization is responsible for the fact that the loading and unloading curves show sharp differences (i.e., there is high hysteresis).

At low deformation (< 10 %), carbon black filled natural rubber exhibits a small loss factor (tan δ) because of the homogeneous carbon black distribution and the uniform network, so that hysteresis losses are low. This means that on small deformations the vulcanizates undergo low heat buildup.

Raw rubber dissolves (or at least swells very strongly) in many organic liquids such as benzene, petroleum ether, crude petroleum, and carbon tetrachloride. In contrast, vulcanized natural rubber can only swell because the chemical cross-linking prevents dissolution.

Compared with synthetic rubber, natural rubber has the following advantages: high structural stability with high elasticity, very good cold flexibility, excellent dynamic properties, and acceptable abrasive wear. Because of this combination of properties, it is superior to synthetic rubber in many applications. Its disadvantages include low oil resistance and unsatisfactory aging properties. In many cases, however, the latter can be improved significantly by the addition of stabilizers.

9. Uses

The main area of use of natural rubber is tires, particularly for trucks, where its property profile makes it much more suitable than synthetic rubber. Because of the low heat conductance, heat buildup is important in large tires. When the elasticity of rubber is too low and the hysteresis too high, too much heat is evolved and heat buildup occurs. This leads to inner burning, which causes destruction of the tire.

Because of its high elasticity associated with low hysteresis, natural rubber is also used in spring elements and buffers.

10. Modification

Since 1801, natural rubber (NR) has been modified in many different ways, and modified forms have been available commercially since 1915. The degree of modification can vary from a few percent to complete modification of the polymer chain.

Modification highly affects physical properties. Even thermoplastic or resinous material can be obtained by modification of rubber.

The most well known types of modification are hydrogenation,chlorination,hydrohalogenation, cyclization, resin modification, methyl methacrylate grafting, superior-processing *N*-phenylcarbonylazoformate modification (see Section 10.8), polystyrene grafting, and epoxidation.

In addition, degraded natural rubber (liquid NR) and thermoplastic natural rubber (TP-NR) exist. Liquid NR is a chemically degraded natural rubber and a true modified rubber, whereas TP – NR is a physical blend of rubber with polypropylene. It is a new form of a thermoplastically processible natural rubber and not a real modification.

10.1. Hydrogenated Natural Rubber

[43–48]

Hydrogenated natural rubber is of purely academic interest. It was first produced by Pummerer and Burkard in 1922 and Harries in 1923, using platinum as hydrogenation catalyst. Further synthetic routes were found by Staudinger and coworkers in 1930. Hydrogenated natural rubber is a colorless, transparent, elastic to waxy solid.

Elastic hydrogenated natural rubber could, in principle, be used in the cable industry because of its good insulating capacity, as well as a raw material for adhesives. However, the relatively high cost of hydrogenation has thus far prevented any commercial applications.

10.2. Chlorinated Natural Rubber

[49–57]

Chlorinated natural rubber was the first modified natural rubber for which industrial applications were developed. Chlorination can be carried out in solution, in the latex, or on solid rubber. The chlorination mechanism was first investigated by Kraus and Reynolds and later by Bloomfield.

The glass transition temperature of chlorinated natural rubber increases with increasing chlorine content. Up to 35 wt % chlorine the material is still a rubber. Chlorinated natural rubber is more thermally stable and has a clearly higher oil resistance than pure natural rubber. Products with the *trade names* Alloprene (ICI), Parlon (Hercules), and Pergut (Bayer) with a chlorine content of ca. 65 % are available commercially. These products are crumbly materials that no longer possess rubbery properties. They are light, cream-colored, thermoplastic powders, which are nonflammable and highly resistant to chemical attack. They are used in paints and coatings that are resistant to chemicals and protect against serious environmental damage. Chlorinated rubber is dissolved in a solvent and mixed with plasticizers and pigments. These types of paint contain 10 – 12 % chlorinated rubber and can be painted or sprayed on. They are used to protect wood, steel, and cement, and for underfloor protection in car bodies and other vehicles.

Chlorinated rubber is also used in adhesives and textile coatings. However, in many areas it has been replaced by polychloroprene.

10.3. Hydrohalogenated Natural Rubber [58–63]

Hydrohalogenation can be carried out with hydrogen chloride, bromide, iodide, or fluoride. Only hydrogen chloride is used industrially. The hydrobrominated product is very unstable, the hydrogen iodide addition has thus far aroused little interest, and HF is highly toxic.

As early as 1900, WEBER found that natural rubber reacted with hydrogen chloride in chloroform. He obtained a very hard, white product with the molecular formula $(C_5H_9Cl)_x$. Hydrochlorination was further investigated in 1942 by BUNN and GARNER. They discovered that the addition of hydrogen chloride to polyisoprene gives an anti-Markovnikov product. Products with varying degrees of chlorination were synthesized by many others. The hardness of the products increases with increasing chlorine content. Completely hydrohalogenated rubber is a highly crystalline material, which assumes highly ordered structures when elongated and has a *mp* of $> 115\,°C$. It is very inert chemically and completely incompatible with natural rubber.

The largest area of use in the past was in a transparent film with the trade name Plio-Film, which was used as a packaging material, particularly for foods. Hydrohalogenated natural rubber was used as a binding agent between rubber and metals. In 1950, ca. 3500 t was produced. Hydrohalogenated natural rubber is, however, no longer available commercially.

10.4. Cyclized Natural Rubber [63–71]

Cyclized natural rubber is probably the oldest known modification of natural rubber. In 1791, LEONHARDI discovered that rubber becomes hard and brittle when treated with sulfuric acid. Similar observations were made at the beginning of the 1920s, but only in 1927 did FISCHER investigate thoroughly the reaction of natural rubber with organic sulfonic acids, sulfonyl chloride, and sulfates. At the same time BRUSON, SEBRELL, and CALVERT found that cyclized rubber is also obtained from reaction of natural rubber with zinc chloride. The mechanism of this internal cyclization is not completely understood. A suggestion based on the results of M. GORDON was worked out in 1956 by BLOOMFIELD and STOKES.

Two types of cyclized rubber were formerly produced commercially:

Products Obtained by Cyclization with Sulfuric Acid or its Derivatives. These cyclized products were subdivided into two further classes, depending on the degree of modification.

1) Brown-black, resinous substances similar to balata materials. They were sold by Goodrich under the names Thermoprene and Fenolac, and were used as adhesives, binding agents, and reinforcing resins.
2) Light, transparent, low molecular mass resins. They were soluble in many solvents and were compatible with many other resins, oils, and plasticizers. The commercial products were Plastoprene from Plastanol and Alpex 450 J from the Societa Italiana Resine. They were used for printing inks and surface varnishes, in particularly for products requiring resistance to chemicals.

Products Obtained by Cyclization with Chlorostannic Acid. The second group of products included thermoplastic, fusible materials, which were sold by Goodyear under the name Plioform. Other commercial products were masterbatches, which were sold by Durham Raw Materials under the name Cyklite and by Hubron Rubber under the name Cyklatex. They were used for shoe soles and nonblack heavy-duty industrial rollers.

10.5. Resin-Modified Natural Rubber [72–74]

Resin-modified natural rubber is not a modified rubber in the classical sense. It is formed by reaction of natural rubber with phenol – formaldehyde resins during vulcanization. Very soft vulcanizates to ebonite-type materials (hard rubber) can be produced. The products have a wide range of applications and are available, for example, under the name Cellobond from BP Chemicals. They have a low compression set, excellent dynamic stability,and good aging properties. Moreover, with reinforcing carbon

black (→ Carbon, Chap. 6.7.) (e.g., N 330) the Mooney viscosity is not increased, which improves processibility.

10.6. Poly(Methyl Methacrylate)-Grafted Natural Rubber [75–85]

Several monomers can be grafted onto natural rubber (e.g., styrene, vinyl acetate, acrylonitrile, and methyl methacrylate). Peroxides or hydroperoxides are used as initiators. The most important graft polymers are those with methyl methacrylate that are marketed under the trade name Hevea Plus MG. Their main areas of use are in self-reinforcing vulcanizates and adhesives. Three qualities of Hevea Plus MG are available commercially: MG 30 with a total content of 30 wt % methyl methacrylate, MG 40 with 40 wt %, and MG 49; the latter consists of 80 % graft polymer, 10 % free methyl methacrylate, and 10 % free polyisoprene. MG 49 is miscible with natural rubber and common carbon blacks in almost all proportions and can be vulcanized with normal sulfur cross-linking systems. About 300 – 500 t of all types is produced per year.

One use of these materials is for poly(vinyl chloride) adhesion. For this application a free-flowing powder form of Hevea Plus MG 49 is available, which dissolves rapidly in toluene or methyl ethyl ketone.

10.7. Superior-Processing Natural Rubber [30–33]

Superior-processing natural rubber is a mixture of vulcanized and unvulcanized natural rubber. The cross-linking occurs in the latex and was investigated in detail by the Rubber Research Institute of Malaysia in 1957. Products are available with 20 – 80 wt % vulcanized phase in the mixture. They are characterized by better processibility, particularly in injection molding. After mixing the vulcanized and unvulcanized latices, they are coagulated and dried together in the normal way. The products are SP 20, SP 40, SP 50, PA 57, and PA 80. The PA products, which contain more than 50 % of the vulcanized phase, are available only as masterbatches. They are used as process materials in rubber processing. The masterbatches do not contain any fillers but are stretched with oil. PA 57 is a variant of PA 80 stretched with 40 wt % oil, so that there is 57 % cross-linked rubber, 15 % unmodified rubber, and 29 % oil in the final product. Unlike other process materials, SP rubber does not alter the properties of the final vulcanizate. It leads only to improvements in calendering, extrusion, and injection molding. In calendering, these improvements include smoother surfaces, less shrinkage, and reduced temperature sensitivity of the mixture. Also, in continuous salt vulcanization the addition of PA 80 helps to prevent problems of porosity.

10.8. *N*-Phenylcarbamoylazoformate-Modified Natural Rubber [86–93]

Like the hydrogenated analogue, natural rubber modified with ethyl *N*-phenylcarbamoylazoformate (ENPCAF) is of scientific interest only. Many scientists have investigated this modification and its mechanism of formation. No commercial applications have yet been found.

10.9. Polystyrene-Grafted Natural Rubber [94–101]

Polystyrene-modified natural rubber was developed for the production of a thermoplastic elastomer. Thermoplastic elastomers frequently have an ABA block structure, where A is styrene (see Rubber, 3. Synthetic). The desired structures cannot be obtained by a common grafting process, as used for grafting with methyl methacrylate. A longer route via special polystyrenes having azodicarboxylate as the terminal group must be used. With simultaneous disintegration of the azo groups a polymer of defined structure is formed, but not a pure ABA block. Since thermoplastic natural rubber is also obtained through blends of natural rubber with polyolefins, the graft products with styrene have not gained any commercial importance.

10.10. Epoxidized Natural Rubber (ENR) [102–115]

The trialkylethylene double bonds of natural rubber readily undergo a reaction with peracids to give epoxides in high yield. This is the most economical method of modifying natural rubber at the latex stage. A mixture of hydrogen peroxide and formic acid, for example, can be used for the epoxidation. The mechanism was extensively investigated by GREENSPAN and GONSOVSKAJA after the reaction had been discovered by PUMMERER and BURKARD in 1922. A 100 % epoxidized natural rubber is a thermoplastic with a glass transition temperature of ca. 100 °C and can be processed by injection molding.

Products epoxidized to 10 – 50 % are commercially available under the names ENR 25 and 50. These products can be cross-linked by using normal vulcanization agents.

The glass transition temperature increases by ca. 1 °C per mole of epoxidation per mole rubber, so that ENR 50 has a T_g near room temperature. ENR 50 is a highly damped rubber at room temperature and at higher temperature it has the same resilience as natural rubber itself. The oil resistance is improved significantly with increasing degree of epoxidation, compared to natural rubber, whereas the gas permeability decreases. Because of this the use of epoxidized products as inner liners in tires has been investigated. However, the degree of modification must be 70 % to achieve the same gas permeability as butyl rubber, and the products are then no longer rubbery and therefore unsuitable for the purpose envisaged. Another application that is being tested is the reinforcement of NR with light fillers, for which epoxidized natural rubber is used as binding agent. These vulcanizates have the same mechanical properties as natural rubber vulcanizates with highly reactive carbon blacks, but they exhibit improved resistance to skidding in the wet and a lower resistance to rolling. Another potential area of use is improvement of the impact resistance of polystyrene. No commercial breakthroughs have occurred in any of these areas, however.

10.11. Degraded Natural Rubber [116–118]

Liquid NR is a dark, viscous material obtained by depolymerization – oxidation of natural rubber with peroxides in a kneader. STEVENS registered the first patent in 1933. The products are sold under the trade names Lorival R 525 and 200, and Hartmann DPR 35, 40, 75, 400, and 01. Their molecular masses vary between 13 000 and 160 000 g/mol.

These products are used as rubber processing materials and are incorporated into the network, so that they do not lead to any significant deterioration of the properties of the vulcanizate.

10.12. Thermoplastic Natural Rubber [119–126]

As already mentioned, thermoplastic natural rubber can be obtained either by grafting with polystyrene or by blending with polyolefins. Products based on blends are available commercially (→ Rubber, 3. Synthetic).

11. Compounding

Like all rubber, for natural rubber the property profile of the vulcanizate depends considerably on compounding. Hardness can be increased as desired by the addition of *inactive fillers* (chalk, kaolin, etc.), with decreases of toughness and elasticity. With *semiactive carbon blacks* a good compromise is achieved among good processibility, low compression set, relatively high hardness, and good toughness. For very high requirements concerning toughness and abrasive wear, *highly active fillers* must be used (highly active carbon black, light fillers with SI 69). To improve the processibility and lower the cost of compounding, *plasticizers* are added. Because of the sensitivity toward oxidation, *aging* and *ozone protection agents* are also necessary.

Vulcanization is carried out by using sulfur and vulcanization accelerators (e.g., dimorphyl disulfide) or with resin systems, depending on the area of use.

Depending on the use, substances can also be added for flameproofing, increasing the building tack, improving tear resistance, etc.

12. Summary [127]

Natural rubber is the most important rubber in terms of quantity produced because of its excellent mechanical properties (and will also remain so, at least in the medium term). The annual consumption is ca. 5×10^6 t, which is 35 % of the total world rubber consumption. The growth between 1970 and 1990 amounted to 65 %, and the growth forecast for the next five years is 1.7 % annually.

Since the retail prices have been relatively low, they should be maintained at this level by the International Rubber Agreement or at least be kept within certain limits.

Countries in which natural rubber is cultivated are attempting to achieve higher yields from their production by increasing the refinement of further processing of NR, in addition to continuous efforts to improve yields (kilograms per hectare). How successful this will be is not known. If the wage level in the producer countries increases in the long term, NR will be replaced increasingly by synthetic rubber because of rising prices. Only in applications where, for example, extremely high resistance to tear propagation is required (medical gloves, condoms, etc.) will NR not be replaced, even at a much higher price.

Abstract

The article contains sections titled:

1. Introduction
1.1. Market and Areas of Application
1.2. Nomenclature and Classification
1.3. Properties
1.4. Production
1.5. Producers
2. Emulsion Rubbers
2.1. Emulsion Styrene - Butadiene Rubber (E-SBR)
2.1.1. Properties, Grades, and Application
2.1.2. Basic Chemistry and Production Processes
2.1.3. Producers and Production Capacities
2.2. Chloroprene Rubber (CR)
2.2.1. Properties, Grades, and Applications
2.2.2. Basic Chemistry and Production Processes
2.2.3. Producers and Production Capacities
2.3. Nitrile Rubber (NBR)
2.3.1. Properties, Grades, and Applications
2.3.2. Basic Chemistry and Production Processes
2.3.3. Producers and Production Capacities
2.4. Emulsion Polybutadiene (E-BR)
2.4.1. Properties and Applications
2.4.2. Basic Chemistry and Production Processes
2.4.3. Producers and Production Capacities

2.5. Acrylate Rubber (ACM)
2.5.1. Properties, Grades, and Applications
2.5.2. Basic Chemistry and Production Processes
2.5.3. Producers and Production Capacities
2.6. Fluororubbers
2.6.1. Chemical Composition and Properties
2.6.2. Vulcanization
2.6.3. Production Processes
2.6.4. Producers, Production, Capacities, and Markets
3. Solution Rubbers
3.1. Synthesis by Anionic Polymerization
3.1.1. Solution 1,3-Butadiene - Styrene Rubber (S-SBR) and Styrene - Isoprene - Butadiene Rubber (S-SIBR)
3.1.1.1. Properties, Grades, and Applications
3.1.1.2. Basic Chemistry and Production Processes
3.1.1.3. Producers and Production Capacities
3.1.2. Lithium - Butadiene (Li-BR) and Lithium - Isoprene (Li-IR) Rubber
3.1.2.1. Properties, Grades, and Applications
3.1.2.2. Basic Chemistry and Production Processes
3.1.2.3. Producers and Production Capacities
3.2. Synthesis by Ziegler - Natta Polymerization
3.2.1. Polybutadiene and Polyisoprene Rubber
3.2.1.1. Properties, Grades, and Applications
3.2.1.2. Basic Chemistry and Production Processes
3.2.1.3. Producers and Production Capacities
3.2.2. Ethylene - Propene Elastomers (EPM, EPDM)
3.2.2.1. Properties, Grades, and Applications
3.2.2.2. Basic Chemistry and Production Processes
3.2.2.3. Producers and Production Capacities
3.3. Synthesis of Butyl Rubber by Cationic Polymerization
3.3.1. Properties, Grades, and Applications
3.3.1.1. Properties
3.3.1.2. Grades
3.3.1.3. Specialty Rubbers
3.3.1.4. Applications
3.3.2. Basic Chemistry and Production Processes
3.3.2.1. Basic Chemistry
3.3.2.2. Industrial Production
3.3.3. Producers and Production Capacities
3.3.4. Storage and Transportation
3.3.5. Legal Aspects
3.3.6. Toxicology and Occupational Health
4. Synthesis by Radical and Other Mechanisms
4.1. EVM and Ethylene Copolymers
4.1.1. Properties, Grades, and Applications
4.1.2. Basic Chemistry and Production Processes
4.1.3. Producers and Production Capacities
4.1.4. Toxicology
4.2. Epoxide Rubbers (CO, ECO, GECO, GPO)
4.2.1. Properties, Grades, and Applications
4.2.2. Basic Chemistry and Production Processes
4.2.3. Producers and Production Capacities
4.3. Polynorbornene
4.3.1. Production of 2-Norbornene Monomer
4.3.2. Polymerization
4.3.3. Properties
4.3.3.1. Properties of Pure Polymer
4.3.3.2. Properties of Polynorbornene Rubbers (PNR)
4.3.4. Processing of PNR
4.3.5. Uses
4.3.6. Economic Aspects
4.3.7. Toxicology
4.4. Polyoctenamers
4.4.1. Production of Cyclooctene
4.4.2. Polymerization
4.4.3. Properties
4.4.4. Vulcanization, Processing, and Applications
4.4.5. Economic Aspects
4.4.6. Toxicology
5. Synthesis by Polyaddition, Polycondensation, and Other Mechanisms
5.1. Silicone Rubber
5.1.1. Properties, Grades, and Applications
5.1.2. Production Process and Basic Chemistry

5.1.3. Producers and Markets
5.2. Polyurethane Rubber
5.3. Thiokol Rubber
5.3.1. Properties, Grades, and Applications
5.3.1.1. History
5.3.1.2. Grades
5.3.1.3. Mechanical Properties, Cross-Linking, and Applications
5.3.2. Basic Chemistry and Production Processes
5.3.3. Producers and Production Capacities
6. Synthesis by Polymer Modification
6.1. Halobutyl Rubber
6.1.1. Introduction
6.1.2. Properties, Grades, and Applications
6.1.3. Basic Chemistry and Production Process
6.1.3.1. Basic Chemistry
6.1.3.2. Production
6.1.4. Chemical Analysis
6.1.5. Storage and Transportation
6.1.6. Legal Aspects
6.1.7. Producers and Production Capacities
6.1.8. Toxicology and Occupational Health
6.1.9. New Commercial Development
6.2. Chloropolyethylene and Chlorosulfonyl Polyethylene
6.2.1. Chloropolyethylene
6.2.1.1. Properties, Grades, and Applications
6.2.1.2. Basic Chemistry and Production Processes
6.2.2. Chlorosulfonyl Polyethylene
6.2.2.1. Properties, Grades, and Applications
6.2.2.2. Basic Chemistry and Production Processes
6.2.3. Producers and Production Capacities
6.3. Hydrogenated Nitrile Rubber
6.3.1. Properties, Grades, and Applications
6.3.2. Basic Chemistry and Production Processes
6.3.3. Producers and Production Capacities
6.4. Polyphosphazenes
6.4.1. Properties, Grades, and Applications
6.4.1.1. Properties
6.4.1.2. Commercial Grades and Applications
6.4.2. Basic Chemistry and Production Processes
6.4.3. Producers and Markets
7. Thermoplastic Elastomers
7.1. Introduction
7.1.1. Definition
7.1.2. Global Market
7.2. PVC Blends
7.3. Thermoplastic Polyurethanes
7.4. Styrene Block Copolymers
7.5. Thermoplastic Polyolefins
7.6. Copolyesters
7.7. Copolyether- and Copolyetheresteramides
8. Evaluation of the Present Situation and Remarks on Future Trends
8.1. Market, Producers, and Capacities
8.1.1. Market
8.1.2. Producers, Capacities and Capacity Utilization
8.2. Market Requirements and Impact on Development of Synthetic Rubber
8.2.1. Tires and Tire Rubber
8.3. Production Processes
8.4. Ecological and Health Aspects
8.4.1. Introduction
8.4.2. Health Aspects
8.4.2.1. Raw Materials
8.4.2.2. Processing
8.4.2.3. Use
8.4.3. Environment
8.4.3.1. Recycling
8.4.4. Outlook

1. Introduction

Desmond Threadingham and Werner Obrecht

1.1. Market and Areas of Application

In 1996 the combined annual consumption of synthetic (SR) and natural rubber (NR) was 15.6×10^6 t worldwide. Consumption grew by 9.5 % in the five years since 1991. The SR and NR consumption in the various regions is shown in Table 1 [1]. For many years, up to 1990, two thirds (ca. 67 %) of the total rubber consumed was synthetic and one third natural rubber. The years from 1991 to 1996 have seen the proportion of SR consumption decline to 63.1 %. This is explained by a large decrease in consumption (– 52.6 %) by CIS and Central Europe (the former Soviet Union and Eastern Europe), which in 1996 still consumed 86.8 % SR. At the same time, a strong increase in consumption (+ 24.4 %) is observed in Asia in Oceania. These include the major NR producing countries of the world, where only 50.6 % SR is used. These influences were partly offset by strong growth (+ 26.1 %) in North America, recovering from recession and a decline in consumption in 1991. In North America 73 % SR is used, which is similar to the European figure (71 % SR).

Table 1. Actual consumption of synthetic and natural rubber in various regions, and forecasts until 2000 (10^3 t) [1].

Region	Synthetic rubber				Natural rubber				Total rubber			
	1994	1995	1996	2000	1994	1995	1996	2000	1994	1995	1996	2000
North America	2 854	3 002	3 026	3 112	1 067	1 116	1 112	1 102	3 921	4 118	4 138	4 214

Total	9 397	9 541	9 849	10 889	5 343	5 618	5 758	6 432	14 740	15 159	15 607	17 321

The areas of SR application and their proportion of total consumption (percent) are as follows.

Tires	59
Automotive mechanical goods	10
Nonautomotive mechanical goods	9
Plastic modification	6
Footwear	4
Construction	3
Wire covering	2
Adhesives	1
Others	6

These figures reflect a strong dependence of SR consumption on tire and automotive production. Table 2 shows the quantity of rubber used (compounded and vulcanized), rubber type, and area of application in a typical medium sized car.

Table 2. Use of rubber in a typical medium size car

Elastomer type	kg per vehicle (gross weight)	Applications
SBR	16.7 (14.9)**	tire, mount, brake hose (tube), coolant hose
BR	6.5 (6.5)**	tire
NR	8.4 (4.0)**	tire, mount, bush, mat, wiper blade
IIR	3.0 (2.9)**	tire, tube, mount
CR	3.1	hose (cover), boot (joint dust cover), fan belt
NBR (HNBR)	2.3	filler neck hose, fuel line hose (tube), power steering hose (tube), oil seal, diaphragm, emission control hose, timing belt
EPDM	5.7	coolant hose, weatherstripping, cable cover, gromment, exhaust hanger
ECO (epichlorohydrin)	0.5	hose (cover), emission control hose, diaphragm
CSM (chlorosulfonyl polyethylene)	0.5	hose (cover), cable cover
ACM (polyacrylate)	0.2	oil seal, oil hose, emission control hose
FPM (fluoroelastomer) *	0.2	diaphragm, fuel line hose (tube), O-ring
Urethane	boot (joint dust cover)	
FVMQ	diaphragm	
Total	47.1	

* For abbreviations of types of rubber, see Section Nomenclature and Classification.
** Figures in brackets indicate rubber used for tires.

1.2. Nomenclature and Classification

In addition to the first SRs which were developed in the 1920s and 1930s and which are still in use nowadays, a variety of more than 20 products now exists, most of them having been developed after World War II [2], [3]. Synthetic rubber can be classified in groups according to the chemical composition of the polymer backbone. These groups can be further subdivided with respect to the substituent groups attached to the polymer chain. The group designation is given in Table 3 [4].

Table 3. Group designation of rubber according to the chemical composition of the polymer chain [4].

Group designation	Chemical structure	Examples
M	rubber having a fully saturated polymer backbone of the polymethylene type	EPM, EPDM, CM, CSM, AEM, ACM, EVM
O	rubber having oxygen atoms in the polymer backbone (polyether rubber)	CO, ECO, GPO
Q	rubber having silicon atoms in the polymer backbone (silicon rubber)	VMQ, MQ, FMVQ
R	rubber having an unsaturated carbon main chain	NR, SBR, BR, NBR, CR, IIR
T	rubber having sulfur in the polymer backbone (polythioether rubber)	OT, EOT
U	rubber of the polyurethane type containing carbon, oxygen, and nitrogen in the polymer backbone	AU, EU
Z	rubber having phosphorus and nitrogen in the polymer backbone	FZ, PZ

This nomenclature allows synthetic rubbers to be identified by a series of letters. The letter indicating the group is the last and is preceded by one or more additional letters representing the name of the monomer or monomers from which the rubber is manufactured. Based on this system the following abbreviations listed below are used for the different types of rubber according to DIN/ISO 1629 [4].

ACM. copolymer of ethyl acrylate or other acrylates and a small amount of a monomer that facilitates vulcanization
[a] *A-CSM.* chlorosulfonated polyethylene with a high content of alkyl groups
[a] *AEM.* copolymers of ethyl acrylate or other acrylates with ethylene
AU. polyester urethane
BIIR. brominated isobutene – isoprene copolymers (bromobutyl rubber)
BR. butadiene rubbers
CIIR. chlorinated isobutene – isoprene copolymers (chlorobutyl rubber)
CM. chlorinated polyethylene
CO. polychloromethyloxirane(epichlorohydrin rubber)
CR. chloroprene rubber
CSM. chlorosulfonated polyethylene
[a] *E-BR.*

emulsion butadiene rubber
ECO. ethylene oxide (oxirane) and epichlorohydrin (chloromethyloxirane) copolymer
[a] *ENM.* copolymer of ethylene and acrylonitrile
[a] *ENR.* epoxidized natural rubber
EPDM. terpolymer of ethylene, propene, and a diene with the residual unsaturated portion of the diene in the side chain
EPM. ethylene – propene copolymer
[a] *E-SBR.* emulsion styrene – butadiene rubber
EU. polyether urethane
[a] *EVM.* ethylene – vinyl acetate copolymer
FMQ. silicone rubber having fluorine and methyl groups on the polymer chain
FMVQ. silicone rubber having fluorine, methyl, and vinyl substituents on the polymer chain
FPM. rubber with fluoro, fluoroalkyl, or fluoroalkoxy substituents on the saturated carbon main chain
FZ. polyphosphazene rubber having fluoroalkyl or fluoroalkoxy substituents on the polymer chain
GPO. copolymer of propylene oxide and allyl glycidyl ether
HIIR. halogenated butyl rubber (halobutyl)
HNBR. hydrogenated acrylonitrile – butadiene rubber (highly saturated nitrile rubber)
IIR. isobutene – isoprene copolymers (butyl rubber)
IR. isoprene rubber, synthetic
MQ. silicone rubber having only methyl substituents on the polymer chain, such as dimethyl polysiloxane
NBR. acrylonitrile – butadiene rubber
PMQ. silicone rubber having phenyl and methyl substituents on the polymer chain
PNR. polynorbornene rubber
PZ. polyphosphazene rubber with phenoxy substituents on the polymer chain
SBR-HS. styrene – butadiene rubber with high styrene content
[a] *S-SBR.* solution styrene – butadiene rubber
[a] *S-SIBR.* solution styrene – isoprene – butadiene rubber
[a] *TPE.* thermoplastic elastomer
VMQ. silicone rubber having both methylvinyl and vinyl substituent groups on the polymer chain
XNBR. carboxylated acrylonitrile – butadiene rubber
XSBR. carboxylated styrene – butadiene rubber
YAU. thermoplastic polyester urethane
YEU. thermoplastic polyether urethane
YSBR. block copolymer of styrene and butadiene
YSIR. block copolymer of styrene and isoprene
[a]. Not officially approved by DIN/ISO 1629 [4].

According to market shares and prices three different categories of SR are usually distinguished [5]:

1. General-purpose or tire rubber
2. Special rubber
3. Speciality rubber or high-performance elastomers

General-purpose rubber. includes various types of rubber with a high market volume that are available at a modest price. This category consists of the R rubbers NR, SBR, BR, and IR that are used mainly in tires. The annual consumption of each of the general-purpose rubbers is > 1×10^6 t (NR: 5×10^6 t; SBR: > 2.5×10^6 t; BR and IR: > 1×10^6 t).

Special rubber includes a series of products that are higher priced and produced in smaller volumes than general-purpose rubber. Representatives of this category are EPDM, NBR, CR, and IIR.

These products are superior to general-purpose rubber in at least one property:

EPDM	good heat and weather resistance
NBR	good oil resistance
CR	medium oil and good ozone resistance, low flammability
IIR	low air permeability

With the exception of IIR, the special rubbers are used for a variety of technical rubber goods such as extruded profiles, seals, gaskets, hoses, or power transmission belts. IIR and its halogenated derivatives — BIIR and CIIR — are used primarily for tire inner liners and tubes because of their low air permeability. The annual consumption of each special rubber is in the range 200 000 – 650 000 t.

The group of *high-performance elastomers* (speciality rubber) consists of small-volume, high-priced products. These products are distinguished by at least two major properties. Examples are

FPM. excellent oil and heat resistance
VMQ. excellent low-temperature flexibility and excellent heat resistance
HNBR. excellent dynamic performance combined with good heat and oil resistance

As for special rubbers, the most important application of high-performance elastomers is in technical rubber goods. Apart from silicon rubber with an annual consumption of more than 100 000 t, the annual consumption of the other high-performance elastomers is generally less than 100 000 t each.

1.3. Properties

SR is superior to natural rubber primarily in two properties; its heat and mineral oil resistance [6-13]. A classification of elastomers according to their heat and mineral oil resistance is shown in Figure 1 (plot according to ASTM D 2000/SAE J 200) [14], [15].

Figure 1. Classification of elastomers according to their heat and oil resistance

To enable a better overall comparison of properties, low-temperature flexibility, mechanical properties, ozone resistance, and price must also be considered (see Table 4). The data and ratings given in Table 4 are based on literature values [7-16]. In spite of various difficulties associated with a quantitative rating of complex properties, marks ranging from 1 – 10 are assigned to each of the technological properties evaluated: 1 reflects poor and 10 reflects outstanding performance. However, the rating marks do not always correlate with the data on specific properties given in Table 4. This is because the data refer to single physical properties that can be quantified rather easily, whereas the ratings refers to technological performance which accounts for many different aspects. It has to be considered that the technological performance of filled vulcanizates is highly influenced by the compounding ingredients and the vulcanization system used. Since the rating marks must account for various properties, they are not really objective from a scientific point of view. On the other hand, Table 4 and Figure 2 provides a summary of relevant technological properties and a guideline for comparing various elastomers.

Table 4. Comparative rating of properties in filled vulcanizates (1 poor and 10 outstanding performance)

Rubber	Low-temperature performance		Maximum service temperature		Mechanical performance		Oil swell (ASTM 2000–90)		Ozone resistance rating	Overall performance index	Price, $/kg	Performance – price ratio
	T_g, °C	Rating	T_{max}, °C	Rating	Tensile strength, MPa	Rating	vol % (T, °C)	Rating				
NR	–72	8	80	1	25	10	>140 (70)	1	1	21	1.3	16.2
SBR	–70/+10	6	95	3	22	7	130 (70)	2	1	19	1.1	17.3
BR	–120/–70	10	85	2	20	6	>140 (70)	1	1	20	1.1	18.2
EPDM	–60/–45	5	145	6	24	8	>140 (70)	1	8	28	1.8	15.6
IIR	–60	6	135	5	15	3	140 (70)	1	6	21	2.3	9.1
NBR	–70/+10	5	125	5	22	7	5 – 60 (100)	7	2	26	1.8	14.4
CR	–39/–35	4	115	4	22	7	80 (100)	3	6	24	2.7	8.8
CM	–25	3	140	6	15	4	80 (150)	4	5	22	2.6	8.5
CSM	–25	3	135	5	16	4	80 (150)	4	9	25	4.0	6.3
EVM	–35/+10	4	170	8	14	3	20 – 100 (150)	6	9	30	3.3	9.1
AEM	–35	4	170	8	15	4	50 (150)	5	9	30	7.3	4.1
ECO	–50	5	130	5	15	4	30 (150)	6	8	28	7.8	3.6
AU	–30	4	80	1	25	10	3 – 25 (100)	7	9	31	6.9	4.5

VMQ	–120	8	250	10	10	1	30 – 50 (150)	6	10	35	9.9	3.5
ACM	–45/–10	4	170	8	14	3	20 – 40 (150)	7	9	31	7.7	4.0
HNBR[a]	–26/ –34	3	150	6	25	10	15 – 40 (150)	8	9	36	25.0	1.4

FZ	–65	8	180	8	16	4	10 (150)	9	10	39	500.0	0.1

[a] Fully hydrogenated grades.

Figure 2. Performance and price of elastomers

The rating marks assigned to *low-temperature performance* (Table 4) account for T_g, rate and degree of crystallization, and compatability with plasticizers. The T_g values given in Table 4 refer to raw rubber [11].

The *maximum service temperature* referred to in Table 4 is the temperature at which a 50 % decrease in elongation is observed for an aging period of 1000 h. The temperature is usually obtained by extrapolation in an Arrhenius-type plot assuming the validity of a linear relation. The data quoted in Table 4 are from [11-15] and are based on static hot-air aging tests.

The data on *tensile strength* (TS) in Table 4 are chosen as one feature characterizing the mechanical performance of a vulcanizate. Again, tensile strength is only one aspect of mechanical performance. Other important properties are elongation at break, moduli at different extension ratios, resistance to cut growth, abrasion, dynamic performance, elasticity, and hysteresis loss (the latter two are determined by static and dynamic experiments over a wide temperature range). Data on tensile strength are primarily based on [11-13]; the ratings given for mechanical performance are based on [16].

Oil-swell data given in Table 4 refer to ASTM D 2000 [14] and SAE J 200 [15]. These data refer to volume swell of the corresponding vulcanizates after 70 h immersion in ASTM oil 3 for the temperature given in brackets. The ratings account for the volume swell and the influence of oil additives commonly used.

For an overall evaluation of elastomer performance, *outdoor performance* must be taken into account. To provide comparative data, ozone resistance seems appropriate [6]. The ratings given in Table 4 are based on [16].

The *overall performance index* given for each elastomer is the sum of five performance ratings. Thus the overall performance index of the “ideal elastomer” is 50. As Table 4 shows, even the best elastomers have overall performance indices well below 50.

Price is often referred to as the most important technological property. Because synthetic raw rubber prices strongly depend on the price of crude oil, the competitive situation, and marketing factors, the data given in Table 4 do not have absolute significance but are comparative figures.

A performance – price evaluation for various rubbers is given in Figure 2; here the overall performance indices are plotted versus the respective raw rubber prices (data from Table 4). As can be seen from this figure, simple economic features are verified. No products are available that provide either outstanding performance at low cost or low performance at a high price.

1.4. Production

The great variety of manufacturing processes for SR can be classified from both a chemical and from a chemical engineering point of view. Chemically, the mechanism governing the polymerization reaction and the chemistry involved in the key reaction are important. However, technologically speaking, the process and the series of process steps involved are major issues. In Table 5 the most important synthetic rubbers are listed according to both chemical and chemical engineering criteria. All important polymerization mechanisms are applied to SR: free-radical, Ziegler – Natta, anionic, and cationic polymerizations, as well as polyaddition and polycondensation. More recently, modification of readily available polymers has become an established route for the production of SR. Technologically important methods for chemical modification of existing polymers are chlorination and bromination of butyl rubber (CIIR and BIIR), chlorination and chlorosulfonation of polyethylene (CM and CSM), hydrogenation of NBR (HNBR), and alcoholysis of polyphosphazenes (FZ).

Table 5. Production of synthetic rubber in terms of chemical mechanisms and process features [*]

Chemical mechanism	Process features				
	Emulsion	Solution	Dispersion	Bulk	Gas phase
Radical polymerization	E-SBR; CR; NBR; E-BR; ACM; FPM; EVM	EVM	EVM	AEM; EVM (ENM)	
Ziegler – Natta polymerization		BR; EPM; EPDR	EPM; EPDM	EPM; EPDM; EPDM (BR)	(EPM); (EPDM)
Anionic polymerization		BR; S-SBR; IR		Q	
Cationic polymerization		ECO; CO	IIR	Q	
Polyaddition and polycondensation		AU; EU	EU	AU; Q	
Polymer modification		CIIR; BIIR; CM; CSM; HNBR; FZ	CM; CSM (HNBR)		

* Processes under development are given in parentheses.

The production technology includes both well-established and more advanced processes. Emulsion, solution, and dispersion processes are well established. More advanced technologies are bulk- and gas-phase processes that are as yet applied only to a few synthetic rubbers when the corresponding manufacturing facilities are available for large-volume products such as thermoplastics. For example, AEM and EVM are polymerized in bulk by using the technology developed for low-density polyethylene production. The bulk copolymerization of ethylene and acrylonitrile (ENM) is not yet applied in commercial-scale production and commerical-scale production of EPDM by the gas-phase process is only now in 1997 being introduced to the market by Union Carbide. The gas-phase process omits several of the steps (i.e., storage and purification of solvents, solution makeup, reactor cooling, solvent flashing and recovery, polymer washing, cleaning and drying) in a typical production sequence. The simplified process should reduce energy requirements and offer the potential for 20 – 30 % cost reduction. At the same time the Du Pont Dow joint venture is building new capacities to produce EPDM using a metallocene catalyst system. This single site catalyst provides a more similiar polymerization reaction rate for ethylene, propene, and ethylidene norbornene. Hence, a more consistent polymer with better distribution of the monomers along the polymer chain is produced while the constrained geometry of the catalyst environment results in a polymer which is more linear. The greater catalyst efficiency means that only minute traces of catalyst remain in the polymer. Therefore, a water washing step to clean the polymer is dispensed with in the new process, which allows cost savings and avoids problems which arise sometimes from residual moisture in the polymer [17] (further references are given in Section Production Processes, Table 64)

Table 64. Capacities, capacity shares, and plant locations of the top 11 producers of synthetic rubber according to 1995 IISRP statistics *

Company	Production capacity for solid rubber, 10^3 t	Share of total SR capacity, %	Location of plants
Bayer	911	11.9	United States, Canada, Germany, Belgium, France
Enichem	668	8.7	Italy, United Kingdom, United States
Goodyear	630	8.2	United States, France
Exxon	622	8.1	United States, France, United Kingdom, Japan
JSR	580	7.6	Japan
Shell	470	6.1	United States, France, Japan, Netherlands, Germany
Nippon Zeon	380	4.9	Japan, United States, United Kingdom
DSM	370	4.8	Netherlands, United States, Japan
Korea Kumho	355	4.6	South Korea
Du Pont Dow	354	4.6	United States, United Kingdom, Japan
Bridgestone / Firestone	260	3.4	United States

* Figures refer to Western World capacities; latex, TPE, and specialities are not included.

.

As outlined in Table 5, different routes exist for the production of various types of synthetic rubber.

The specific features and advantages of various processes and the product properties that are associated with these processes are the focus of the following chapters. Despite the very different synthetic and technological routes applied in the production of SR the same sequence of process steps is generally used:

1. Storage of raw materials and feedstocks
2. Purification of raw materials and feedstocks
3. Making up solutions and mixing of components
4. Polymerization or polymer modification reactions
5. Short stopping
6. Flashing, degassing, and stripping of unreacted monomers, solvents, and other components
7. Stabilization
8. Postmodification reactions (blending with oil, carbon black, polymers, fibers, etc.)
9. Polymer isolation, cleaning, and drying
10. Finishing of polymer, including baling, pelletizing, and packaging

Additional process steps that are not included in the straightforward production scheme are

1. Recycling of monomers, solvents, and catalysts
2. Treatment of waste air and wastewater
3. Treatment of scrap

As a consequence of economic and environmental constraints, these aspects are gaining increasing importance. To avoid additional costs for waste air and wastewater treatment, even well-established processes are currently being analyzed and improved. Economic and environmental aspects will have a great impact on future developments.

1.5. Producers

Due to takeovers, the start-up of new plants, and plant closures the range of products being supplied from various SR manufacturers has changed considerably since the early 1980s. The respective product portfolios of the major SR suppliers are listed in Table 6. Latex, TPE, and E-BR are not included in this list.

Table 6. Major manufacturers of synthetic rubber outside the former Eastern Bloc and their range of solid rubber grades *

SR producer	Range of solid rubber grades
Bayer	AU; BIIR; BR (Co, Li, Nd, Ti); CIIR; CR; EPDM; EPM; E-SBR; EVM; HNBR; IIR; NBR; Q; SBR-HS; S-SBR, XNBR
DSM	EPDM; EPM; E-SBR; NBR
DuPont	AEM; CM; CR; CSM; EPDM; EPM; EVM; EU; FPM

ENI	ACM; BR (Li, Nd, Ti); CR; EPDM; EPM; E-SBR; FPM; NBR; SBR-HS, S-SBR
Exxon	[BR(CO)]; BIIR; CIIR; EPDM; EPM; [E-SBR]; EVM; IIR
Goodyear	BR (Ni); [EPDM]; [EPM]; E-SBR; IR; NBR; SBR-HS; S-SBR; XNBR
JSR	ACM; BR (Ni); EPDM; EPM; E-SBR; [IIR]; IR; NBR; SBR-HS; S-SBR
Korea Kumho	BR (Ni); [EPDM]; E-SBR; NBR; SBR-HS; S-SBR
Michelin	BR (Ti); E-SBR; SBR-HS; S-SBR
Nippon Zeon	ACM; BR (Co); CO; ECO; E-SBR; GPO; HNBR; IR; NBR; PNR; SBR-HS; S-SBR; XNBR

* Latex and TPE are not included; products available from joint ventures are given in square brackets.

2. Emulsion Rubbers

Werner Obrecht, Jean-Pierre Lambert, Michael Happ, Christiane Oppenheimer-Stix, John Dunn, Ralf Krüger

2.1. Emulsion Styrene – Butadiene Rubber (E-SBR)

In 1929, the first copolymer of styrene and butadiene was synthesized in the Bayer laboratories by E. TSCHUNKUR and W. BOCK [18] using an emulsion polymerization process. By 1935, the production of the polymer, called Buna S, had reached 25 t per month. In the original process, the polymerization temperature was 50 °C, allowing the use of potassium persulfate as activator. Sodium linoleate was used as emulsifier but acted also as a chain-transfer agent (molar mass regulator). The styrene content of the polymer was ca. 30 wt %. The end product was difficult to process and had to be softened by heat at 130 °C before use. A significant improvement was made in 1942 when the linoleic soap was replaced by a saturated sodium fatty soap as emulsifier and diisopropyl xanthogen disulfide as chain-transfer agent. Softening by heat treatment was also required for this new grade called Buna S3 [19], [20]. The properties and the manufacturing process of Buna S were well known in the United States where research had been conducted in the same area.

At the beginning of World War II the U.S. government initiated a program to produce large amounts of styrene – butadiene copolymer known as “Government Rubber-Styrene” (GR – S). The first plant went on stream in April 1942. In this process dodecyl mercaptan was used as chain-transfer agent, which resulted in a rubber that did not need to be softened by heat. In 1945, the following production capacities were available:

Germany: 175 000 t/a;
United States: 840 000 t/a.

In 1947, the use of the “redox initiation system” allowed a reduction in polymerization temperature from 45 to 5 °C, resulting in a rubber that was much easier to process. Essentially the same “cold polymerization process” is in use in 2003. New forms of E-SBR (oil-extended SBR, black masterbatches, SBR pre-cross-linked with divinylbenzene) were introduced in the late 1940s and early 1950s. Almost all families of E-SBR marketed in 2003 were commercially available by 1954: hot and cold grades including masterbatches with black or oil [21], [22] and cross-linked types. Due to its excellent cost – performance – processing balance, E-SBR in 2003 still has — after more than 50 years — a much larger market share than any other synthetic elastomer, and represents more than 30 % of the synthetic rubber produced worldwide. It is the main synthetic elastomer used for tire manufacturing, which accounts for about 75 % of its usage [23]. However, its usage is slowly decreasing, because polybutadiene and solution SBR are more and more preferred for tire construction [24]. New derivatives of conventional E-SBR are currently being introduced in the market and could counteract that decrease.

In addition, some technological changes took place in E-SBR production to reduce possible health hazards.

2.1.1. *Properties, Grades, and Application*

Compared to other elastomers, E-SBR offers the following advantages:

1. Excellent abrasion resistance,
2. Good physical properties including crack growth resistance, good elasticity, and good stress – strain properties.
3. Excellent water resistance.
4. Easy processing.
5. Adjustable low-temperature flexibility.

Disadvantages are:

1. Medium heat resistance,
2. Poor resistance to organic chemicals,
3. Poor ozone resistance,
4. Low green strength and building tack,
5. Insufficient performances when using silica as reinforcing filler.

E-SBR starts to decompose at ca. 200 °C. Its flash point varies from 210 °C for the oil-extended grades to more than 300 °C for the non-extended grades. All E-SBRs have an autoignition temperature higher than 300 °C (ASTM D 1929). The typical rubber density varies from 0.94 g/mL for a nonextended polymer (23.5 wt % styrene) to 1.13 g/mL for a black oil masterbatch. The glass transition temperature increases with the bound styrene content. It is less than – 30 °C with 40 wt % of styrene and increases to – 20 °C for a styrene content of 50 wt % [26].

Main Families of E-SBR. Many individual grades of E-SBR are produced by using different combinations of variables such as polymerization temperature, presence of a cross-linking agent, ratio of styrene to butadiene, type of emulsifier and antioxidant, use of extender oils, or masterbatching with carbon black. The International Institute of Synthetic Rubber Producers (IISRP) has issued a nomenclature for these grades, assigning a four-digit number to each of them [27]. All the grades are classified in sections. Rubbers that belong to the same sections have the first two digits of the grade number in common.

Section 1: Hot Nonpigmented Rubber (grades 1002 to 1028). These grades offer an improved green strength and a good processibility. They are used in applications such as adhesives and cements [28], light-colored mechanical goods, or chewing gum. The cross-linked grades prepared by adding a third monomer (ethylene glycol dimethylacrylate or divinylbenzene) during polymerization, are also used as process aids when blended with general-purpose rubber. They improve the production rate and aspect in extruded and calendered goods.

Section 2: Cold Nonpigmented Rubber (grades 1500 to 1573). These grades are produced in a large range of viscosities with highly varying contents of bound styrene. They are used in applications such as adhesives, belting, footwear, mechanical goods, tire carcasses, treads, wire, and cable insulation.

Section 4: Cold Oil Masterbatch (grades 1700 to 1779). This form of E-SBR is very popular and represents more than 50 % of the E-SBR sold in the United States. These polymers have a higher molar mass and are extended with aromatic, naphthenic, or paraffinic oils at levels varying from 16 to 50 wt % based on the polymer (16 to 50 parts per hundred rubber, phr). They combine low cost with good physical properties (due to high molar mass of the ESBR used), easy processing, and improved building tack. They are used in a wide number of applications (tires, belting, footwear, hoses, mechanical goods, etc.).

Sections 3 and 5: Cold Oil – Black Masterbatch (grades 1601 to 1622 and 1805 to 1849). The number 16 (section 3) and 18 (section 5) families contain

carbon black and can contain oil. The oil content can vary from 0 to 30 phr for the 16 family and from 17.5 to 62.5 phr for the 18 family. These oil – black masterbatches are made from various elastomers (here E-SBR) carbon black, and oil types. They are used mainly in the tire industry. For the rubber processor, they offer the advantage that carbon black need not be added during processing, and that the number of mixing steps is reduced.

Emulsion Resin–Rubber Masterbatch and High-Styrene Reinforcement Polymers (grades 1900 to 1960). These polymers generally contain more styrene than the conventional E-SBR grades (up to 85 wt %) and are used in a wide range of applications where high hardness is required (e.g., for footwear and packaging).

New Products. In addition to the conventional grades, all known since the 1960s, several new experimental polymers belonging to the E-SBR family are in 2003 said to be available, but have not been reportedly sold in big volumes:

- NSBR: In that grade proposed by Bayer part of the styrene monomer is replaced by acrylonitrile. NBR has been proposed for manufacturing both technical goods and tires [29].
- Functionalized E-SBR and NSBR: Polymers functionalized with mainly hydroxyl and amino groups have been prepared. This modification improves the quality of the reinforcement, mainly when white fillers such as silica are used [30-34].
- E-SBR with a low soap content: The high residual soap level contained in E-SBR is detrimental to reinforcement. E-SBR preparation with a low residual soap has been patented [35].

Uses. E-SBR can be used alone or in blend with other polymers such as butadiene rubber to decrease the rolling resistance of tires, or it can be blended with natural rubber to improve its green strength [36]. It is compounded by using the same basic formulations as applied for other unsaturated hydrocarbon polymers. Sulfur, accelerators, zinc oxide, stearic acid, antioxidants, fillers, and softeners are generally present in the compound.

2.1.2. *Basic Chemistry and Production Processes*

E-SBR was the first commercial polymer produced by emulsion polymerization (⟶ Polymerization Processes). The mechanisms specific to E-SBR synthesis are described here briefly for the case of cold polymerization:

Generation of free radicals

$$\underset{\text{Hydroperoxide}}{ROOH} + \underset{\text{Ferrous ion}}{Fe^{2+}} \longrightarrow \underset{\text{Peroxyl radical}}{RO^{\bullet}} + \underset{\text{Ferric ion}}{Fe^{3+}} + OH^{-}$$

Initiation

$$RO^{\bullet} + \underset{\text{Butadiene}}{CH_2{=}CH{-}CH{=}CH_2} \longrightarrow RO\,(CH_2CH{=}CHCH_2)^{\bullet}$$

Propagation

$$RO(CH_2CH{=}CHCH_2)^{\bullet} + C_6H_5CH{=}CH_2 \rightarrow RO\left(CH_2CH{=}CHCH_2\right)(C_6H_5CH{-}CH)^{\bullet}$$

the growing chain can be designated $P^{\bullet}$

Chain transfer

$$P^{\bullet} + \underset{\text{Mercaptan}}{RSH} \longrightarrow PH + RS^{\bullet}$$

Chain termination by combination

$$P^{\bullet} + P^{\bullet} \rightarrow P{-}P$$

Chain termination by disproportionation

$$P^{\bullet} + P^{\bullet} \rightarrow P^{1} + P^{2}$$

Activation. Several systems have been proposed for initiation of the radical polymerization to form E-SBR. For high-temperature E-SBR (40 – 60 °C), radicals are formed by decomposition of ammonium or potassium persulfate. For the production of E-SBR at lower temperature, hydroperoxide – sugar and peroxide – iron – potassium pyrophosphate systems were first used as activators [37]. In 2003, the peroxide – iron – ethylenediaminetetraacetic acid complex – reducing agent (sodium formaldehyde sulfoxylate) system is largely favored [38].

Chain Transfer. A chain transfer agent (also called molar mass modifier), generally a long-chain tertiary mercaptan, is added to the reactor to regulate the molar mass of the polymer. Because its concentration controls the average molar mass of the polymer produced at each instant, its depletion rate must be adjusted to the polymerization rate. This is often achieved by the use of incremental modifier addition or by using mercaptans with different molar masses (C_9- to C_{16}-mercaptans are commercially available) [39].

Shortstopping. The reaction is stopped between 60 and 80 % conversion, depending on the required rubber properties. Dithiocarbamates, hydroquinones, and hydroxylamines are generally used for this purpose. Dithiocarbamates which were largely used for shortstopping until the late 1990s have generally been substituted by other compounds to avoid the build-up of carcinogenic nitrosamines. The role of the shortstopper is to scavenge radicals and eliminate excess activator still present at the end of the polymerization.

Production Process. (see Fig. 3). E-SBR can be produced batchwise or continuously. That latter process, the most commonly used, is described here: Styrene, butadiene, soap, water, modifier, and the components of the activation system are pumped into a reactor train at a controlled rate. The soaps used for manufacturing E-SBR are “natural” soaps such as tallow fatty acid soap or disproportionated rosin soap (nonmodified rosin soaps act as reaction retarders). Generally the reaction is performed in six to twelve well-agitated reactors. Since the reaction temperature greatly influences polymer structure and thus properties (see Table 8), the heat removal system (jacket, cooling plates, tubes, external exchanger) must be carefully designed if a high content of *trans*-1,4-moieties is to be obtained (reaction temperature 5 °C).

Figure 3. SBR production — simplified flow chart

a) Precooler; b) Polymerization reactor; c) Fluid refrigeration unit; d) Blowdown tank; e) Atmospheric flash tank; f) Vacuum flash tank; g) Stripping column; h) Latex blend tank; i) Coagulation tank; j) Soap conversion tank; k) Wash tank; l) Dewater extrudes; m) Dryer; n) Baler; o) Weighscale

Reactor size varies from 10 to 30 m^3. Activator and modifier are sometimes added incrementally to control reaction kinetics and improve the copolymer properties.

When the target conversion is reached, the reaction is stopped and unreacted monomers are recovered. In the standard process, that operation is performed in three steps: In the first and second steps, the latex is flashed in two drums (the first one being at atmospheric pressure and the second one under vacuum at ca. 10 kPa). The latex is then pumped to the top of a stripping column, operating under vacuum, the latex passing downward over perforated plates countercurrent to steam.

The latex is then generally stored before being pumped to *coagulation*. The antioxidant and, in the case of masterbatch production, oil emulsion and carbon black slurry are added before coagulation. The oil used as extender can be aromatic or naphthenic. In the case of aromatic oils, the trend is to reduce the content of carcinogenic polycyclic aromatic hydrocarbons (PAH) to less than 3 wt % by using “mildly refined paraffinic” (MES) or “treated distillate aromatic extracts” (TDAE) oils. Coagulation usually takes place in two well-agitated tanks. During this operation the rubber is precipitated, usually by a mixture of sulfuric acid and brine with the addition of a small amount of animal glue or polyamines to improve the coagulation. Other possibilities are to use multivalent metal ions (calcium, aluminum, magnesium) or “salt-free” systems in which cationic flocculants are used in combination with acid, resulting in rubber with a low ash content. The rubber is then rinsed in a reslurry tank, dewatered in a dewatering extruder or on a vacuum drum filter, and dried by using either a thermal (tunnel, fluidized bed) or an extruder dryer. The rubber crumbs are finally baled and packaged.

Control of the Polymer Structure. Due to the free-radical polymerization process, E-SBR is a random copolymer and its structure can only be statistically controlled. The viscosity of the rubber increases with increasing molar mass. Table 7 illustrates the dependence between the Mooney viscosity ML 1 + 4 at 100 °C and the molar mass *M* measured by gel permeation chromatography. The butadiene moiety, as incorporated in the polymer chain, can form three isomers with *trans*-1,4-, *cis*-1,4-, and 1,2-linkages.

Their respective proportions can be controlled only by varying the reaction temperature. The lower the reaction temperature, the higher the percentage of *trans*-1,4-units (see Table 7) [23].

Table 7. Relationship between Mooney viscosity and molar mass *

	Mooney ML 1 + 4		
	34	**53**	**108**
Molar mass, 10^3 g/mol	350	500	850

* Measurements performed in the Bayer laboratories.

Table 8. Proportion of different structure types as a function of polymerization temperature

Reaction temperature, °C	*cis*-1,4-Units, %	*trans*-1,4-Units, %	1,2-Units, %
5	8	69	23
50	15	58	27

Branching density in E-SBR increases with butadiene content and conversion. Polymer chains start forming gels if more than one branch per chain is formed. Therefore the probability of gel formation increases with butadiene content, conversion, and molar mass [40]. The styrene content of the copolymer depends on the styrene – butadiene ratio in the feedstock. Due to the reactivity ratio r_1 and r_2 of styrene and butadiene, 0.476 and 1.413 at 15 °C [40], [41], the copolymer composition drift during polymerization is limited and there is no need to add any of the monomer incrementally during E-SBR polymerization (see also ⟶ Plastics, General Survey – Copolymerizations).

2.1.3. *Producers and Production Capacities*

There is a large overcapacity for E-SBR production: In 1995, less than 2×10^6 t was manufactured worldwide, although production capacity then was reported to be more than 4×10^6 t. The main suppliers are listed in Table 9 [41].

Table 9. Major suppliers of E-SBR and production capacity (individual capacity over 20 000 t; data from 2003)

Company name	Plant location (s)	Capacity, t
DSM Copolymer Inc	United States	150 000

2.2. Chloroprene Rubber (CR)

2.2.1. *Properties, Grades, and Applications*

Polychloroprene [(poly(2-chloro-1,3-butadiene)] [9010-98-4] was first produced in 1932 by Du Pont under the name Duprene. Besides butyl rubber (IIR), nitrile rubber (NBR), and ethylene – propylene – diene rubber (EPDM), CR is among the most important special rubbers in terms of quantity produced [42-44].

Polychloroprene vulcanizates are characterized by the following combination of the technical properties:

1. Good mechanical strength
2. High ozone and weather resistance
3. Good aging resistance
4. Low flammability
5. Good resistance toward chemicals
6. Moderate oil and fuel resistance
7. Adhesion to many substrates

Polychloroprene can be vulcanized by using various accelerator systems over a wide temperature range. Because of its favorable properties, polychloroprene is used in the following areas:

1. In the rubber and cable industry (ca. 73 %)
2. As a raw material for adhesives (ca. 17 %)
3. As a latex (ca. 10 %)

Industrially, polychloroprene is produced by radical polymerization of chloroprene (2-chloro-1,3-butadiene) (⟶ Chlorinated Hydrocarbons) in aqueous emulsion. The reaction is exothermic (ΔH = – 65 to – 75 kJ/mol). Chloroprene polymerizes 700 times faster than other dienes such as isoprene. The high reactivity of chloroprene favors homopolymerization. Copolymers with the following monomers are important economically:

1. 2,3-Dichloro-1,3-butadiene for rubber grades with a high degree of crystallization [25067-95-2]
2. Esters of acrylic and methacrylic acids with di- and polyhydric alcohols for the production of pre-cross-linked grades
3. Elemental sulfur for the production of sulfur-modified grades
4. Unsaturated carboxylic acids (particularly acrylic and methacrylic acids) for carboxylated latices and solid rubber grades [25053-30-9]

In radical polymerization the individual chloroprene moieties are incorporated into the polymer chain in various structures (see Fig. 4). In addition to the dominating 1,4-*trans*-structure, also 1,4-*cis*-, 1,2-, and 3,4-units can be detected by NMR [45]. In the 1,4-*trans*-moiety the neighboring monomer units can be bonded head-to-head, tail-to-tail, or head-to-tail. The proportions of the individual structures in the polymer strongly depend on the polymerization temperature (see Table 10). Structural irregularities increase with rising polymerization temperature. At the same time, the degree and rate of crystallization decrease. If CR is used as a *raw material for adhesives*, high degrees of crystallinity are desirable [25]. In this case the polymer is produced at 30 °C in the absence of crystallization-distorting monomers. Films produced from solutions of such types of adhesives exhibit high cohesive strength after a short period as a result of crystallization. Hence these grades are particularly suitable for the production of contact adhesives.

Table 10. Proportions of different structure moieties in polychloroprene as a function of the polymerization temperature

Polymerization	1,4-*trans* *			1,4-*cis*	1,2	3,4

* H = head; T = tail.

Figure 4. Incorporation of chloroprene units into the polymer chain

In *CR rubber grades*, however, crystallization is undesirable because it leads to an increase in the hardness of unvulcanized rubber mixtures on storage and a decrease in the elasticity of the vulcanizate through embrittlement [46]. At polymerization temperatures between 30 and 65 °C, crystallization can be inhibited. However, polymerization at these temperatures increases the proportion of the 1,2-structure (allylchloro structure) in the polymer chain (see Table 10). These groups are of decisive importance because vulcanization with metal oxides (in particular ZnO and MgO) occurs via the 1,2-structures, but they also promote aging of the rubber. Allylchloro structures are also formed by incorporation of 1-chloroprene, which is present as an impurity in 2-chloroprene. To produce CR rubber grades that crystallize very slowly, polymerization is performed in the presence of crystallization-distorting comonomers (in particular 2,3-dichloro-1,3-butadiene). Two main polychloroprene grades exist: the *solid rubber grades* for elastomers and adhesives, and the *latex grades.* The solid rubber grades are classified according to crystallization tendency and viscosity (solution viscosity for adhesives, Mooney viscosity for rubber articles).

Solid Rubber title.
Elastomers. Elastomers consist of general-purpose grades, pre-cross-linked grades, and sulfur-modified grades. *General-purpose grades* are mostly produced with *n*-dodecylmercaptan as the chain-transfer agent and occasionally with xanthogen disulfides. If xanthogen disulfides are used, the elastomers are more readily processible and give vulcanizates with improved mechanical properties, such as higher tensile strength and resistance to tear propagation. This improved performance allows the incorporation of higher levels of filler in the compounds and thus makes them cheaper [47].

Pre-cross-linked grades consist of a blend of soluble CR (sol) and cross-linked CR (gel). The gel particles are finely dispersed in the rubber matrix. Pre-cross-linked rubber mixtures show less swelling after extrusion (die swell), better calenderability and surface smoothness, and higher dimensional stability under load. Pre-cross-linked grades are particularly suitable for the extrusion of profiled parts.

Sulfur-modified grades are copolymers of chloroprene and sulfur. The viscosity is adjusted mostly after polymerization by cleavage of polysulfide bonds with thiuram disulfides under alkaline conditions (peptization). With a special method, so-called in situ peptization, polymerization and chain cleavage occur in parallel, supported by nucleophiles such as dithiocarbamates or xanthates.

Sulfur-modified grades can be masticated readily (lowering of viscosity) and thus allow the production of soft mixtures with good building tack. Vulcanization can be carried out with MgO and ZnO alone without an accelerator, because the terminal groups introduced by peptization are involved in the curing mechanism. Sulfur-modified grades are used in particular for parts exposed to dynamic stress, such as driving belts, timing belts, or conveyor belts, because of their excellent mechanical properties. The low stability of the raw rubbers to storage and the low hot air resistance of the vulcanizates represent disadvantages compared with general-purpose grades. The most important areas of application for elastomers in Western Europe in 1990 were as follows (in percent):

Molded goods	25 %
Cable	14 %
Transmission belts	8 %
Profiles	7 %
Conveyor belts	3 %
Others	14 %

Adhesives. The CR grades with moderate or high crystallizing tendency are used for adhesives. Special grades contain thiuram compounds, which accelerate production of the adhesive solution by rapid mastication. The most important areas of application for contact adhesives based on polychloroprene are in shoe sole adhesion; gluing of veneers in the furniture industry; adhesion of floor coverings; and do-it-yourself work with wood, textiles, and other materials.

Latex Grades. The latex grades are classified according to the crystallization tendency, type of emulsifier, deformation hardness, solubility of the dry substance, pH of the latex, and coloration tendency. A special grade, a carboxylated latex (e.g., with methacrylic acid as the comonomer), vulcanizes with ZnO even at room temperature. The most important uses of CR latex are:

1. Binding agents for all types of fibers
2. Impregnating, coating, and lining woven tissue
3. Molded foam (e.g., for chair upholstery and mattresses)
4. Improvement of bitumen
5. Dipped articles (e.g., meteorological balloons and rubber gloves)
6. Elastic concrete

2.2.2. *Basic Chemistry and Production Processes*

Polychloroprene is produced exclusively by radical polymerization in aqueous emulsions, mainly between 10 and 45 °C [42]. Polymer properties are determined primarily by the nature and quantity of the chain-transfer agent, the final degree of conversion, the polymerization temperature, and if present, the comonomers.

Other parameters primarily affect *colloidal properties*, but also alter polymer structure indirectly. These are mainly the nature and concentration of emulsifiers and coemulsifiers, the electrolyte concentration, the ratio of liquid monomer phase to aqueous phase, the kind of activation, and the polymerization process. Polymerization is carried out either continuously in a cascade of stirred-tank reactors, semibatchwise (continuous addition process), or batchwise in a stirred-tank reactor. Small quantities of special grades are best produced in a batch process. The continuous addition process is most suitable for production of copolymers from comonomers with unfavorable copolymerization parameters.

The emulsion polymerization is performed at pH 9 – 13; alkali salts of disproportionated rosin acids are mainly used as *emulsifiers*. In addition, sodium sulfonates — such as those derived from naphthalenesulfonic acid (e.g., Baykanol PQ) or alkylbenzenesulfonic acids (e.g., Marlon A 365) — are required for the process. When the alkaline latex is acidified for freeze coagulation (see below) the rosinate is converted into the water-insoluble acid, which has no emulsifying action. The sulfonic acids remain in the form of their salts in both the neutral and the weakly acidic pH regions, and maintain the stability of the latex at room temperature. For cationic or neutral latices, which are also applied in the form of latex, cationic emulsifiers such as long-chain ammonium salts or betaines are used, as well as alkyl sulfates or alkyl sulfonates. Chloroprene polymerizes very readily; in particular in the presence of air, it first reacts to form peroxy compounds, which decompose spontaneously and can produce popcorn polymers (i.e., polymers with a popcorn-like shape that are formed especially from dienes. These undesired polymers are formed by proliferous growth, especially in the gas phase at low levels of chain-transfer

agents or in the presence of cross-linkers.). Chloroprene is therefore protected against oxidation and polymerization by the addition of antioxidants, such as 2,6-di-*tert*-butyl-4-methylphenol, phenothiazine, 4-*tert*-butylcatechol, or combinations of these compounds. Nitrogen oxides and their addition products to alkenes or amines are particularly effective for preventing popcorn formation.

In industrial polymerization the stabilizers are generally not removed from the monomers and they are compensated for by suitable activation. The choice of *activator system* is determined mainly by

1. The nature and quantity of stabilizers in the monomer
2. The polymerization temperature
3. The comonomers (e.g., sulfur)
4. The presence of traces of oxygen

Activation with water-soluble persulfates in the presence of sodium 9,10-anthraquinone-2-sulfonate (silver salt) is widely used. At higher temperature (> 300 °C), sulfinic acids (e.g., formamidinesulfinic acid) can also be employed. Traces of oxygen, inhibitors, or aldehydes (which are formed as impurities in the monomer synthesis) can be eliminated by the addition of sodium sulfite. For low polymerization temperatures (< 30 °C), redox initiators (e.g., peroxodisulfate – dithionite) are generally used, sometimes with addition of iron-(II) sulfate and the disodium salt of ethylenediaminetetraacetic acid (EDTA).

In the absence of *chain-transfer agents*, chloroprene polymerizes to form cross-linked, high molar mass products, which cannot be processed even at low degrees of conversion. To obtain soluble polymers and to adjust the viscosity, chain-transfer agents such as *n*-dodecylmercaptan or xanthogen disulfides, must be added and the conversion must be limited to 70 % (max.) [48]. Polymerization is then terminated by the addition of a shortstopper. To protect the rubber against thermal aging, *stabilizers* are frequently also added at this point. The residual monomer is removed by steam distillation in vacuum (stripping) and recycled to the process. The diameter of the latex particles is generally between 100 and 200 nm. The pH of the degassed latex is adjusted to 5.5 – 7.0 by addition of dilute acetic acid. The latex is then coagulated continuously as a thin film on a slowly rotating cooling drum at ca. –15 °C; thawed by spraying with water; and washed, dried, rolled to produce a rope, cut into chips, and packed (Fig. 5). Direct rotary drying without a separate washing step is an alternative, but it is less widely used than freeze coagulation.

Figure 5. Schematic of the production of polychloroprene

a) Polymerization reactor; b) Stripper; c) Purification; d) Neutralization; e) Peptization; f)Rotating cooling drum; g) Coagulation by freezing; h) Latex concentration; i) Chopping machine; j) Dursting machine; k) Roping machine; l) Dryer; m) Washing

Some *latex grades* are concentrated after degassing.

For *sulfur-modified grades*, elemental sulfur is used in the polymerization instead of a regulator. This gives a cross-linked copolymer with chloroprene and sulfur sequences. The polysulfide bonds are peptized in a subsequent step with thiuram disulfide, for example; the reaction is accelerated by, e.g., dithiocarbamates. For *pre-cross-linked grades* the gel component must be polymerized at a high degree of conversion (> 80 %) to achieve sufficient cross-linking densities in the gel latex particles because of the unfavorable copolymerization parameters of chloroprene and the cross-linking agent. The degassed sol and gel latices are mixed and isolated together as solid rubber. In this way a regular distribution of the gel particles in the rubber is achieved.

2.2.3. *Producers and Production Capacities*

Polychloroprene is produced by seven Western producers at nine production sites. The total nameplate capacity is 325 000 t/a [49]. Production sites also exist in China and the former Soviet Union, which produce for their own consumption. Their production figures are estimates (see Table 11).

Table 11. Polychloroprene producers and production sites

Producer	Product name	Production site	Production capacity, t/a	Production started	Notes
Bayer	Baypren	Dormagen/Germany	60 000	1957

2.3. Nitrile Rubber (NBR)

2.3.1. *Properties, Grades, and Applications [50-56]*

Nitrile rubber, acrylonitrile – butadiene rubber, or poly(acrylonitrile-*co*-1,3-butadiene) [9003-18-3] is a special rubber, which gives vulcanizates with a balanced combination of properties. The rubber is readily processed and can be cross-linked with most common vulcanization systems. The vulcanizates exhibit excellent resistance to swelling in oils, fats, and fuels; good hot air resistance; good compression set; and abrasion resistance.

The resistance to swelling is determined mainly by the acrylonitrile content in the polymer. With increasing acrylonitrile content (i.e., higher polarity of the

vulcanizate), its resistance to swelling increases (see Fig. 6). This occurs, however, only in nonpolar or low-polarity media. The NBR vulcanizates are strongly swelled by polar solvents such as esters and ketones. Other industrially important properties are also affected by the acrylonitrile content [57]. With increasing acrylonitrile level, the low-temperature flexibility and elasticity, in particular, as well as the gas permeability, decrease, whereas the hardness, compression set, and tensile strength increase (see Fig. 7). Thus, for certain applications the acrylonitrile content of the starting polymer must be chosen in such a way that the best possible compromise between all properties is achieved. Grades of NBR with an acrylonitrile content of 15 – 53 wt % are available commercially. The most important grades have an acrylonitrile content of 28 – 38 wt %. They possess a balanced ratio of low-temperature flexibility and resistance to swelling. The glass transition temperature T_g of NBR grades with 22 – 51 wt % acrylonitrile is between – 40 and – 12 °C, according to differential scanning calorimetry (DSC) measurements [58]. For NBR grades with acrylonitrile contents of < 34 wt %, two different glass transitions are obtained experimentally, depending on whether the polymer was synthesized with or without staggered monomer dosage [59]. This effect is due to the higher chemical heterogeneity of the polymer. If the T_g is determined by using a dynamic method (vibron viscoelastometer), slightly higher T_g values are found than with DSC depending on the stress frequency [60]. Values of T_g between – 48 and – 1.5 °C were obtained for acrylonitrile contents between 19.2 and 49 wt %.

Figure 6. Swelling (change in weight, ΔG) of NBR vulcanizates versus acrylonitrile content. Immersion temperatures: ASTM oils 140 °C, liquid fuels 20 °C, immersion time 14 days

a) Second-order transition point; b) Brittleness point

The *aging properties* of NBR after aging in hot air are generally better than those of natural rubber, for example. The maximum service temperature for NBR in hot air is ca. 120 °C (according to ASTM-D 2000). After suitable compounding (e.g., by using light fillers such as silica and ether-thioether as plasticizers), short-term heating up to 150 °C can be sustained [61-63]. If air is excluded, NBR vulcanizates are also stable for longer periods at 150 °C [55], [64].

The NBR vulcanizates are used mainly where resistance to oil, fuels, and fats is required (e.g., in the automotive and oil drilling industries). They are chiefly employed for production of technical rubber goods such as seals, O-rings, valves, and bellows. Nitrile rubbers are also used for producing tank and hydraulic hosing, printing and calender rollers, and brake linings.

The molecules of *NBR standard grades* are normally linear or only slightly branched. The molar mass correlates approximately with the melt viscosity, which is given as the Mooney value. Products with low Mooney values (low molar mass) are processed more readily, whereas products with high Mooney values give vulcanizates with better mechanical properties, such as tensile strength, elasticity, and compression set.

The special *cross-linked NBR grades* are produced by copolymerization with a bifunctional monomer, such as divinylbenzene. Compounding of cross-linked grades with standard NBR gives articles with a particularly good dimensional stability, especially after extrusion. The die swell is exceptionally low in these products, and very smooth surfaces are obtained. However, compared with standard grades, these vulcanizates have poorer tensile strength, elongation at break, and resistance to tear propagation.

Another class of special grades are the *carboxylated NBR grades*, *XNBR* [56], [65], [66]. These are acrylonitrile – butadiene copolymers that contain small quantities of a carboxylic acid (e.g., methacrylic acid; acid content up to 9 wt %) [67]. These grades are characterized by improved tensile strength, resistance to tear propagation, and in particular, higher abrasion resistance compared with standard NBR. These improved properties occur because during processing an additional cross-linking occurs via the carboxyl groups in the presence of metal oxides (e.g., ZnO). However, this can also lead to undesirable scorching of the mixture. This problem is counteracted, for example, by use of certain surface-treated types of ZnO or zincperoxide – NBR masterbatches [66]. The addition of sodium stearate to the mixture [68] or cross-linking with epoxy resins [69] has also been suggested. The XNBR rubbers are used mainly in the textile industry (e.g., as spinning cots and aprons) and as pump stators and seals, especially in the oil drilling sector.

An additional class of NBR grades includes those with *bound antioxidants* developed in the 1960s [70-72]. They contain an amine-based antioxidant which is incorporated into the polymer chain by copolymerization. Reportedly, these products have particularly good aging properties on swelling and contact with fuels and oils. They have thus far not been widely used, because they have not brought the expected advantages for all applications. If the vulcanizates are subjected to a so-called sequence aging (i.e., oil-aging followed by hot-air aging), polymers with bound antioxidants show slight advantages. After normal aging marginal improvements are only observed if special compounds are prepared.

To increase the ozone resistance of NBR, *NBR – PVC blends* were developed very early. The proportion of PVC must be at least 30 wt % to achieve a significant effect. A maximum of 50 wt % PVC is used. Either the blends can be produced by mixing the polymers together as solids, or NBR and PVC latices can be co-coagulated before confectioning. Homogeneous mixing of the polymers is essential; this is achieved only if a so-called fluxing occurs between 160 and 170 °C. Only then does a good combination of the resistance to swelling and elasticity of NBR with the good aging and ozone resistance of PVC result [73]. However, the brittleness temperature of the blends increases with increasing amounts of PVC. Such NBR – PVC blends are used mainly in fuel and fire engine hosing, in thermal insulating hosing and in printing rollers.

Further improvement of the aging and ozone resistance of NBR is achieved by *selective hydrogenation* of the double bonds of the butadiene units (see Section Hydrogenated Nitrile Rubber).

Powder grades, a special form of NBR rubber, were developed at the beginning of the 1970s [74], [75]. Baled products are ground to a powder but must then be treated with a dusting agent, such as silica or calcium stearate, to obtain a free-flowing powder. Other processes for the production of NBR powder involve treating NBR latex with a small quantity of a thermoplastic latex (e.g., PVC) followed by coprecipitation. The powder particles are thus coated with a thermoplastic shell, which inhibits their self-adhesion [76]. In another variant the NBR latex is spraydried so that considerable quantities of other latex components remain in the product. This process is used mainly for the production of cross-linked powder grades. Originally a new processing technology (continuous compound production) was to be introduced to the rubber industry with the powder grades. However, thus far this technology has not been able to compete with existing processing procedures. The main applications of the powder grades are in the modification of plastics, particularly of PVC and of phenol – formaldehyde resins.

2.3.2. *Basic Chemistry and Production Processes*

The first synthesis of acrylonitrile – butadiene copolymers was carried out as an emulsion polymerization at IG Farbenindustrie in Leverkusen in 1930. Large-scale industrial production of this new rubber began in Leverkusen in 1934.

The production of NBR essentially involves an emulsion polymerization process consisting of polymerization, degassing, precipitation, washing, drying, and finishing. The production processes of individual NBR producers differ only in the nature of the polymerization process (batch or continuous) or in the

equipment (or equipment combinations) used for subsequent processing steps. Greater differences can be found in the other chemical components used (e.g., emulsifiers, modifiers, initiators, shortstopping agents, and antioxidants). All polymerization processes are performed in the same temperature range.

Industrial polymerization is either a batchwise or a continuous process. *Continuous polymerization* takes place in stirred-tank reactors (see Fig. 8). The operating pressure is between 2 and 7 bar.

The production of the individual grades differs in

1. The monomer ratio
2. The modifier content (see above)
3. The use of other comonomers (e.g., divinyl-benzene as a cross-linking agent or methacrylic acid in the production of XNBR grades)

The monomer ratio determines the acrylonitrile content in the final product. The copolymerization parameters [77] of acrylonitrile and butadiene are so different that the acrylonitrile becomes incorporated into the polymer more rapidly than butadiene. Therefore, sometimes subsequent dosing of the monomer must be carried out during polymerization to obtain a product that is chemically as uniform as possible. Acrylonitrile and butadiene polymerize azeotropically at a monomer ratio of 38 wt % acrylonitrile to 62 wt % butadiene. Thus, if the starting monomers are applied in this ratio, polymer molecules with the same chemical composition are obtained during the entire reaction time.

A good overview of the production of nitrile rubber can be found in [50]. The monomers are first emulsified in water by using one or several emulsifiers or dispersion agents, and polymerization is started by an initiator (Fig. 8 A). Alkali salts of arylalkylsulfonic acids, rosin acids, long-chain saturated and unsaturated (C_{12} – C_{18}) fatty acids, alkylsulfonic acids, alkyl sulfates, and mixtures of these compounds are usually used as emulsifiers or dispersion agents. Redox systems are predominantly used for initiation, i.e., mixtures of organic peroxides, hydroperoxides, or persulfates with reducing agents such as sodium dithionite or rongalite (sodium formaldehydesulfoxylate). Metal salts, such as iron sulfate, are often used as cocatalysts. If the reaction is performed in an alkaline medium, complexing agents such as EDTA or nitrilotriacetic acid are added to keep the iron ions in solution. Polymerization at relatively low temperature (0 – 30 °C) with good space – time yields can be achieved by using such redox systems.

The molar mass of the products is controlled with a modifier, normally a long-chain mercaptan (e.g., dodecylmercaptan or mixtures of various mercaptans containing C_8– C_{16} chains). Xanthogen disulfides are currently of minor importance.

To obtain gel-free products the reaction is usually terminated at 70 – 80 % conversion by using a shortstopping agent (c). The latter can be, for example, a reducing agent, which rapidly destroys the peroxides used as initiators. The polymer radicals growing in the latex particles must also be scavenged. Therefore shortstopping agents that are soluble in both water and organic media are used (sodium dithionite, diethylhydroxylamine, hydroquinone, hydroxyammonium chloride or sulfate, or sodium dimethyldithiocarbamate).

After shortstopping, the pressure of the polymerization vessel is released and the residual monomers are removed by distillation or steam stripping in a degassing tower (d). A stabilizer is then added to the latex to protect the rubber from oxidation during processing and subsequent storage. Sterically hindered phenols or diphenylamines, for example, are used for this purpose. The latter, however, give rubbers that are prone to discoloration.

The stabilized latex is then precipitated by the addition of electrolytes such as NaCl, $CaCl_2$, or $Al_2(SO_4)_3$, also in combination with an acid, either in a tube [78], in a precipitation vessel, or in a screw machine (i). Auxiliary products such as polysaccharides or polyamines [79], methyl celluloses [80], or similar materials are often added during the precipitation. Nitrile rubber latex can also be coagulated with cationic precipitating agents, such as quaternary condensation products from epichlorohydrin and amines. These form insoluble compounds with the anionic emulsifiers and are included in the rubber. Nevertheless, rubber coagulated this way shows markedly better water swelling, even without an additional washing step, compared to rubber coagulated by using classical precipitation electrolytes [81].

The precipitation temperature can be up to 80 °C to produce a crumb structure, which permits efficient washing out of emulsifier or initiator residues. Normally water is removed from the damp rubber in a screw machine (k). The rubber is then dried using fluidized-bed or band dryers (l), for example. A residual moisture content of < 1 % is achieved. The rubber crumbs formed are pressed into bales and packed.

2.3.3. *Producers and Production Capacities*

Since a restructuring of NBR activities has occurred because of the sale or closure of plants by various producers, at the beginning of 1992 only nine NBR producers were in operation, whose capacities were ≥ 10 000 t/a. These are listed in Table 12 in order of capacity [82]. Nitriflex and President Fine Chemicals are assumed to produce mainly for the home market. The Russian plant in Krasnojarsk with an estimated capacity of ca. 100 000 t/a is not listed. Its production is probably entirely consumed domestically. The largest producer of nitrile rubber is Bayer, followed by Nippon Zeon and Goodyear. After them come Enichem and JSR with comparable capacities.

Table 12. NBR producers, sites, capacities, and trade names

Company	Site	Capacity, t/a	Trade name
Bayer	Leverkusen (Germany)	35 000	Perbunan N
	La Wantzenau (France)	33 000	Krynac
	Sarnia (Canada)	20 000	Krynac
Nippon Zeon/Zeon Chemicals	Kawasaki (Japan)	10 000	Nipol
	Tokuyama (Japan)	10 000	Nipol
	Barry (United Kingdom)	11 000	Nipol
	Louisville (United States)	32 500	Hycar
	Akron (United States)	3 000	Hycar
Goodyear	Sandouville (France)	11 000	Chemigum
	Houston (United States)	28 000	Chemigum
Enichem	Porto Torres (Italy)	30 000	Europrene N
Japan Synthetic Rubber (JSR)	Yokkaichi (Japan)	30 000	JSR N
Uniroyal	Painesville (United States)	20 000	Paracryl
President Fine Chemicals	Kaohsiung (Taiwan)	12 000	Nancar

Nitriflex	Duque de Caxias (Mexico)	11 000	Nitriflex
DSM	Baton Rouge (United States)	10 000	Nysyn

The consumption of NBR solid rubber in 1989 was given as 208 000 t by the IISRP [82] (not including the former USSR and the communist countries of Asia and Eastern Europe). At an overall capacity of 330 000 t (not including the former USSR), large excess capacity is available.

2.4. Emulsion Polybutadiene (E-BR)

2.4.1. *Properties and Applications*

In contrast to BR which is produced in solution (anionic polymerization, see Section Lithium – Butadiene (Li-BR) and Lithium – Isoprene (Li-IR) Rubber; Ziegler – Natta polymerization, see Section Polybutadiene and Polyisoprene Rubber), E-BR [9003-17-2] is produced by an emulsion polymerization process where chain propagation occurs via a free-radical mechanism. Therefore, the microstructure of the polymer and the stereospecificity of the reaction cannot be controlled as in the case of Ziegler – Natta or Li catalysis. A typical E-BR, which is polymerized at 5 °C and shortstopped at 50 – 60 % conversion, has the following microstructure: 14 % *cis*-1,4; 69 % *trans*-1,4; and 17 % vinyl groups [83]. Due to this microstructure, E-BR exhibits a T_g around – 80 °C whereas the T_g of high-*cis* Ziegler – Natta BR is < – 100 °C [84]. Another feature associated with the free-radical emulsion polymerization of BR is gel formation. To effectively avoid gel formation the polymerization must be terminated at 50 – 60 % conversion [84].

Due to its relatively high T_g and its gel content, E-BR is rarely used for standard rubber applications such as tires and technical rubber goods. However, undisclosed quantities of E-BR are apparently used by tire manufacturers with a considerable captive or pseudocaptive supply of SR (Goodyear and Bridgestone). Because these E-BR tire grades are not commercially available, little is known about them outside these two tire companies.

E-BR is used predominantly in *rubber toughening* of brittle thermoplastic polymers, the most important of which are styrene – acrylonitrile (SAN) copolymers [85], [86]. BR containing SAN is referred to as acrylonitrile – butadiene – styrene (ABS) (⟶ Polystyrene and Styrene Copolymers). To a lesser extent, E-BR is used for the toughening of poly(vinyl chloride) (PVC), poly(methyl methacrylate) (PMMA) (⟶ Polymethacrylates), polycarbonate (PC), polyamides (PA), and polyesters (PETP, PBT) (⟶ Polymer Blends – Polyesters). All of these BR-toughened thermoplastic materials exhibit a two- or multi-phase morphology, with the BR phase being dispersed in a continuous polymer matrix. To obtain good properties (see below) of the composite multiphase materials, the BR phase must be grafted with a shell that acts as a compatibilizer between the BR phase and the surrounding polymer matrix (⟶ Polystyrene and Styrene Copolymers – ABS Production by Emulsion Polymerization). Important parameters of the BR phase are particle size, particle-size distribution, and cross-linking density. BR particles with diameters ranging from 300 – 500 nm yield a superior combination of toughness, stiffness, and surface gloss [86]. A good balance of properties can also be achieved with a bimodal particle-size distribution of the BR phase. The optimum particle diameters are 100 and 400 nm, respectively [87]. Little is known about the influence of cross-linking density of the BR phase on the technological properties of the composite materials [85], [88], [89].

2.4.2. *Basic Chemistry and Production Processes*

The auxiliary agents used for the production of E-BR are quite common and known from the production of other emulsion rubbers. The most important *emulsifiers* are the sodium or potassium salts of fully or partially hydrogenated fatty acids and of hydrogenated or disproportionated rosin acids, as well as sulfates and sulfonates of alkyl and arylalkyl derivatives. In order to obtain E-BR latices with a monomodal particle-size distribution, special emulsifiers containing two ionogenic groups per molecule are advantageous [90]. For *activation*, inorganic salts such as peroxodisulfates or peroxodiphosphates and organic activators such as dialkyl- and diaryl-based peroxides and hydroperoxides are used. Activation with redox systems is used at low polymerization temperatures. In contrast to the application requirements which the other emulsion rubbers have to meet, the utilization of gel-free E-BR is not essential in the production of ABS. Therefore E-BR is produced at polymerization temperatures above 50 °C, and the reaction is carried out until conversions are achieved that are well above the critical conversion at which gel is formed [86].

Butadiene has a fairly low propagation rate constant k_p [91-93] and the average concentration of radicals per latex particle n [94-97] is usually lower than predicted by the Smith – Ewart theory (n = 0.5) (⟶ Polymerization Processes). As a consequence of these low k_p and n values the overall polymerization rate V_{Br} depends strongly on the number of latex particles N_L as given by the Smith – Ewart relationship

$$V_{Br} = k_p \cdot n \cdot [M] \frac{N_L}{N_A}$$

where [M] is the concentration of monomer within the latex particles and N_A is Avogadro's number. Because of the strong dependence of V_{Br} on N_L the manufacturing processes differ considerably depending on the final diameter of the latex particles to be achieved. Technologically important diameter ranges are 80 – 120 nm and 300 – 500 nm. These two types of latices differ by a factor of 64 in volume. At the same monomer – water phase ratio the latex designed for larger particle diameters must contain considerably less latex particles (theoretically: 1/64). The lower particle number results in an equivalent reduction of the overall polymerization rate (V_{Br}). In practice this difference in V_{Br} is not as distinct as predicted by theory because it is somewhat compensated by higher n values [98], by particle agglomeration during the course of the reaction, and by higher monomer – water ratios. Nevertheless, the production of latices with final particle diameters between 300 and 500 nm requires a much longer polymerization time than the production of latices with diameters between 80 and 120 nm, if a direct, one-step polymerization is applied.

Consequently E-BR containing *large-sized particles* is not exclusively produced in a time-consuming one-step reaction. Two-step processes that include the agglomeration of small-sized latices are quite common.

The BR latices with *small particles* in the 100-nm-diameter region are produced in a one-step polymerization either continuously or batchwise. Safety risks are reduced and space – time performance of reactors is improved by incremental butadiene addition.

One-Step Production of Latices with Large-Sized Particles. For the one-step production of latices with particles in the 300 – 500 nm diameter range, initially a small number of latex particles is required to allow for the maximum growth of each particle. This can be achieved either by carefully controlling the initial stage of polymerizaton or by applying *seed latex technology* [86]. The surface area of each individual latex particle increases considerably during the course of the reaction. Thus emulsifier has to be added incrementally during polymerization to achieve optimal soap coverage of the latex particles and good colloidal stability of the latex. On the other hand, overdosing of emulsifier must be carefuly avoided. This would lead to the formation of second- and third-generation latex particles, resulting in a reduction of the final average diameter and in a drastic viscosity increase. The particle-size distribution of latices produced by this route is usually distinctively narrow.

Two-Step Production of Latices Containing Large Particles. For the two-step production of latices containing large particles, various agglomeration techniques are used. Physical as well as chemical methods of agglomeration are employed. The agglomeration route involves freeze agglomeration [99]. More advanced technologies apply high-pressure homogenization [100-103] and chemical agglomeration. Chemical agglomeration is achieved by changing the pH [104-106], by the addition of poly(ethylene oxides) of appropriate molar mass [107], by the addition of latices bearing hydrophilic groups [108], or by latices with a core – shell structure exhibiting a hydrophilic shell [109]. The particle-size distribution of agglomerated latices is usually broad and often polymodal.

To obtain good properties of the rubber-toughened thermoplastic materials the BR latex has to be grafted [86]. For the details of this process step, see ⟶ Polystyrene and Styrene Copolymers.

2.4.3. *Producers and Production Capacities*

Only limited quantities of E-BR suitable for thermoplast toughening are readily available on the market. One of the few suppliers of BR latex is Bayer Elastomères France (Lillebonne) (BL 2004 and KA 8318).

Vast amounts of E-BR are captively consumed by the ABS manufacturing industry. Major ABS producers in the United States, Japan, and Western Europe are Asahi, ATO, BASF, Bayer, Chemische Werke Buna, Daicel, Denki Kagaku, DOW Chemical, DSM, ENI, General Electric, Japan Synthetic Rubber, Kaneka, Mitsubishi, Monsanto, Sumitomo Naugatuck, Toray, and Ube. Due to the captive supply situation of most ABS producers, E-BR capacities are not published. By taking world ABS capacities (3.15×10^6 t) (⟶ Polystyrene and Styrene Copolymers) and assuming that the average rubber content of ABS is 15 wt % and that all ABS is based on E-BR, the total E-BR capacity can be estimated to be 473 400 t.

2.5. Acrylate Rubber (ACM)

Acrylate (ACM) rubbers, designated under ISO 1629 nomenclature as copolymers of ethyl acrylate or other acrylates and a small amount of a monomer that facilitates vulcanization (see Section Properties, Grades, and Applications) were first commercialized by B. F. Goodrich in 1948. These are specialty elastomers whose heat, oil, and ozone resistance is superior to those of general-purpose rubbers such as NR and SBR. Their manufacture, properties, and applications have been reviewed [110], [111]. The first review contains an extensive list of references, and the latter cites several earlier reviews. Both reviews refer to [112].

2.5.1. *Properties, Grades, and Applications*

Properties. The saturated backbone of ACM rubbers renders them inherently resistant to ozone. The first commercial grades were poly(ethyl acrylate) containing a small amount of comonomer as a cross-linking site because the poly(ethyl acrylate) homopolymer is difficult to cross-link. Normally, the concentration of such cross-linking sites is 1 – 5 wt %. The ACM rubbers can be used for continuous service up to 175 °C and for short periods at 200 °C, the ultimate mode of failure being embrittlement. Their aging resistance is superior to that of CR or chlorosulfonyl polyethylene (CSM), comparable to that of hydrogenated nitrile (HNBR) but not as good as that of silicone rubbers or fluoroelastomers. In their resistance to oil, they are comparable to NBR with medium acrylonitrile content and are also fairly resistant to lubricants (both lubricants according to the API-SF classification and synthetic esters). However, they are not resistant to gasoline or aromatic hydrocarbons and, generally, are not suitable for use in contact with hot water or steam. Acrylic elastomers are valued for their resistance to extreme-pressure gear lubricants containing sulfur because of their saturated backbone.

The major disadvantage of ACM rubber is its low temperature resistance. An ACM that consists primarily of *poly*(*ethyl acrylate*) has a T_g of – 15 °C [110] as determined by differential thermal analysis. Such elastomers begin to stiffen just below 0 °C. Low-temperature properties can be improved by the addition of 5 – 12 phr of plasticizer, but the most effective low-temperature plasticizers are volatile at service temperatures and are extracted by many of the fluids to which polyacrylates are exposed. *Poly*(*butyl acrylate*) has a $T_g \approx$ – 45 °C, but it has much poorer oil resistance than *poly*(*ethyl acrylate*). Consequently, a compromise is sought by copolymerizing ethyl and butyl acrylates. Homopolymers of *2-methoxyethyl* or *2-ethoxyethyl acrylate* combine a low T_g with good oil resistance, but these monomers are expensive. Consequently, those elastomers that are available on the market are copolymers of ethyl, butyl, and 2-alkoxyethyl acrylate plus a cross-linking monomer [113]. In 1991, Japan Synthetic Rubber announced the development of an ACM that is temperature resistant down to – 40 °C. The composition of the polymer has not been divulged [114].

Cross-Linking Monomers. Since the backbone of ACM elastomers is saturated, cross-linking sites must be incorporated during polymerization. Cross-linking monomers that have been evaluated include the following:

1. Vinyl monomers incorporating a labile chlorine atom that can be easily substituted (e.g., 2-chloroethyl vinyl ether, vinyl chloroacetate)
2. Unsaturated carboxylic acids (e.g., acrylic or methacrylic acid)
3. Vinyl monomers containing an epoxy group (e.g., allyl or vinyl glycidyl ethers and acrylic or methacrylic glycidyl esters)
4. Diene monomers [e.g., 5-ethylidene-2-norbornene (ENB)] [115]

The first chlorine-containing monomer used was 2-chloroethyl vinyl ether, which required the use of diamines as curatives. More reactive chlorine-containing monomers permit curing by an alkali-metal soap with sulfur as an accelerator. The disadvantages of these cure sites are that the resulting vulcanizates are corrosive and potentially toxic. These disadvantages are overcome by the use of polymers containing carboxylic or epoxide groups with *n*-octadecyltrimethylammonium bromide as the curative [113]. Curing epoxy ACM with isocyanuric acid – *n*-octadecyltrimethylammonium bromide – 1,3-diphenylurea results in long scorch time, fast cure, and low compression set [116]. *Ortho*-tolylbiguanide is added to control the reaction rate. The use of diphenylguanidine to modify reactivity has also been described [117]. Polymers containing ENB [115] have the advantage of being curable with conventional sulfur systems, which results in excellent storage stability and no mold corrosion.

Most cure systems for acrylic elastomers require an oven postcure for the development of optimum properties, including satisfactory resistance to compression set. In many applications postcuring may be avoided by the use of a soap – quaternary salt cross-linking system in a polymer containing chlorine or carboxyl cure sites [118]. A proprietary delayed-action curative – accelerator complex for polyacrylates has been described that contains a chloroacetyl group as the cure site [119]. This complex permits fast curing with no postcure, good scorch protection, and long storage stability.

Reinforcement and Additives. Acrylate rubbers have low gum strength, and carbon black reinforcement is required to ensure tensile strengths up to 17 MPa. The carbon blacks most commonly used are N550, N539, and N774. Stearic acid is commonly applied as a release agent. Antioxidants are not essential for aging resistance, but diphenylamines with low volatility marginally improve dry heat resistance.

For compounding ACM rubbers, Banbury mixing is generally preferred, because these elastomers tend to stick to the mill. Early addition of reinforcing pigments is recommended, because polyacrylates are soft and thermoplastic and quickly lose shear resistance.

Uses. The major market for ACM rubbers is in automative seals for transmission, pinions, valve stems, oil pans, camshafts, crankshafts, steering systems, wheel bearings and brakes, and in automotive hoses, which may account for as much as 25 % of the usage. Acrylate rubber containing epoxy groups and vulcanized with an isocyanuric acid system that requires no postcure is resistant to heat, automatic transmission fluid (ATF), and oxidized ATF [120]. It can be used for automatic transmission fluid (ATF) hoses. ACM rubbers are also used in adhesives, as impact improvers for plastics, in caulks and sealants, in roof mastics, and in binders for rocket propellants. The latter application arises because the polymers burn readily and leave no ash.

As self-cross-linking dispersions, polyacrylate latices are used as binders for nonwoven fabrics and as flock binders in paper saturation to render it water and oil resistant, in adhesives, in manufacture of needle-felt carpets and carpet underlays, and in textile and leather finishing.

2.5.2. *Basic Chemistry and Production Processes (see also ⟶ Polyacrylates)*

Acrylate monomers may be derived from acetylene, lactic acid, or propene (⟶ Acrylic Acid and Derivatives – Production).

Polymerization is generally carried out by free-radical reaction in emulsion or, in some cases, in suspension. Bulk polymerization is possible but is difficult to control. Solution polymerization of water-soluble monomers produces a viscous cement that is difficult to handle. Initiation by photochemical means or by radiation has been studied in the laboratory but is not used commercially.

Emulsion polymerization (⟶ Polyacrylates – Emulsion Polymerization) may be initiated by persulfates (e.g., potassium persulfate) or by hydroperoxides (e.g., *p*-menthane hydroperoxide). Because acrylates tend to hydrolyze, polymerization should be performed at pH > 7 by using a long-chain alkyl sulfate as emulsifier. The solid product is recovered by conventional coagulation washing and drying with hot air, in vacuum, or by extrusion. Antioxidant need not be added at the finishing stage since the polymer backbone is saturated and resistant to heat and light. The polymers tend to be hygroscopic, and dry storage is recommended.

2.5.3. *Producers and Production Capacities*

The most important producers of ACM rubber are listed in Table 13.

Table 13. Producers, production capacities, and trade names of ACM rubber (Based on data from International Institute of Synthetic Rubber Producers Inc.)

Producer (country)	Production capacity, t/a	Trade name
PROTEX (France)	2 000	Acrylon
Reichold (United States)	500	Tylac
Rohm & Haas (United States)	2 000	76 Res
Zeon Chemicals (United States)	5 300	Hytemp
JSR, Corp (Japan)	unknown	Arex
Nippon Zeon (Japan)	500	Nipol
NOK (Japan)	unknown	Noxtite
Mitsui Toatsu (Japan)	2 500	Polyac
Takeda (Japan)	2 500	Ultrasol
Toa Paint (Japan)	1 300	Acron
Toa Resin (Taipei)	600	Acron

2.6. Fluororubbers [121-123]

Fluororubbers represent a large class of high-performance elastomers with saturated carbon backbones in which, in comparison to conventional rubbers such as EPM, the hydrogen atoms attached to the backbone are partially or completely replaced by fluorine atoms. Compared with their hydrogenated analogues, the stabilities of both the C – F bonds and the fluorinated carbon backbone increase significantly with an increasing degree of fluorination [124]. This explains the outstanding properties of fluororubbers, such as high resistance toward heat, chemicals, ozone and weathering, and low swelling in oils and fuels. Thus, fluororubbers find application at high temperatures and in aggressive media: low temperature applications are, however, limited by their high glass transition temperature, typical values for the vulcanizates being between – 10 and 0 °C (special grades between – 30 and – 20 °C). The primary applications of the finished fluororubber articles (seals, tubing, etc.) are found in the automotive, aviation and space travel industries, in chemical plants, and in flue gas desulfurization plants (bellows expansion joints in piping), i.e., areas in which physical and chemical stability and durability under hostile conditions are required. Thus, fluororubbers find increasing application in areas completely new for rubbers, and are also replacing less resistance rubbers in conventional applications [125].

2.6.1. *Chemical Composition and Properties*

Fluororubbers (FPM) consist of fluorinated ethylene moieties, e.g., vinylidene fluoride (VDF) and tetrafluoroethylene (TFE), randomly copolymerized with fluorinated vinyl comonomers, e.g., hexafluoropropene (HFP) and perfluoro(alkyl vinyl ether) (PFAVE). The function of the comonomers is to disrupt the crystallinity of the fluorinated polyethylene. However, this is accompanied by an undesired increase in the glass transition temperature of the resulting copolymer compared with that of the homopolymer (e.g., PVDF) [126], [127]. A balanced copolymer composition is therefore required. In Table 14 the main types of fluorinated rubbers are listed according to their monomer composition, fluorine and hydrogen content, and their application temperature.

Table 14. Classification of commercial fluororubbers according to monomers, service temperature, and fluorine and hydrogen content

Fluororubber grade [a]	F content, %	H content, %	Service temperature, °C [b]
VDF – HFP	66	1.9	–18 – 210
VDF – HFP – TFE	67 – 71	1.1 – 1.7	–12 – 230
VDF – TFE – PFMVE	64 – 66.5	1.1 – 1.7	–27 – 230
TFE – PFMVE	73	0	0 – 280
TFE – P	54	4.3	5 – 200
TFE – P – VDF	56 – 60	3.1 – 3.7	– 9 [c] – 230

[a] VDF = vinylidene fluoride, HFP = hexafluoropropene, TFE = tetrafluoroethylene, PFMVE = perfluoro (methyl vinyl ether), P = propene.
[b] Region between the glass transition temperature of the raw rubber (T_g's of filled vulcanizates are 3 – 6 °C higher) and the upper maximum service temperature.
[c] According to [123].

The sequence $–CH_2–CF(CF_3)–$, and in particular its dyad and triad, which are found in fluororubbers containing vinylidene fluoride and hexafluoropropene, are especially prone to attack from bases and nucleophiles. The strong electron-withdrawing effect of the CF_3 group facilitates the elimination of HF in the presence of strong bases (e.g., present as oil additives). This leads to formation of unsaturated units in the polymer backbone [128], with subsequent reduction in the chemical and ozone resistance of the rubber [129]. The proportion of these sequences can be reduced by partial or complete replacement of the hexafluoropropene and vinylidene fluoride by perfluorinated monomers: the ageing and swelling porperties of the fluororubbers, and their stability towards bases increase with increasing degree of fluorination. Thus, perfluorinated elastomers, e.g., copolymers of tetrafluoroethylene and perfluoro (methyl vinyl ether), have the highest thermal stability. Alternatively, the resistance of the rubbers to bases can be enhanced by replacing hexafluoropropene with propenes containing less (or no) fluorine, e.g., co- and terpolymers in which the hexafluoropropene is partially or completely replaced by 2-hydropentafluoropropene [123].

The fluororubbers based on tetrafluoroethylene and propene discovered in the 1960s and subsequently marketed (Asahi Glass, tradename: Aflas) [130-133] offer a good alternative to rubbers with high fluorine contents (> 65 %). Despite their lower fluorine content (ca. 54 %), these alternating copolymers have a very high stability toward bases, are resistant toward polar solvents, experience less swelling in methanol [133-135], but suffer from extremely poor low temperature flexibility. A lowering of the glass transition temperature from – 2 °C for the tetrafluoroethylene – propene copolymer by ca. 10 °C, yet with retention of the advantageous property profile, may be achieved by terpolymerizing tetrafluoroetylene – propene with VDF [136]. Furthermore, reactive sites, such as double bonds, can be introduced into the terpolymers, enabling cross-linking reactions [137].

2.6.2. *Vulcanization*

Because of the extraordinary stability of the bonds in the polymer backbone of fluororubbers, the vulcanization step cannot be carried out by using conventional methods.

For *copolymers containing vinylidene fluoride and hexafluoropropene,* vulcanization is possible after reactive groups have been created in the polymer chain in situ by dehydrofluorination [128], [138], [139].

The structural element –CF=C(CF_3)– can be considered as a reactive di- or triene moiety. The fluorine atom attached to the double bond can be replaced by suitable nucleophiles. Cross-linking bridges can be created by the use of bifunctional nucleophiles such as diamines (hexamethylenediamine) or bisphenolates [2,2-bis(4-hydroxyphenyl)hexafluoropropane, i.e., bisphenol AF].

In industrial processing the vulcanization system consisting of bisphenol AF, in combination with magnesium oxide and calcium oxide (acid scavengers) and benzyltriphenylphosphonium chloride (HF elimination catalyst), is most frequently used. Processing does not normally present any problems (good mixture formation, low mold fouling). The resulting vulcanizates are characterized by satisfactory mechanical properties. Typical copolymers of vinylidene fluoride vulcanized with bisphenol have the following tension – extension characteristics: 7 – 17 MPa tensile strength and 150 – 400 % elongation at tear. The compression set values are also low at high temperature: 15 – 30 % after 70 h at 200 °C. Fluororubbers vulcanized in this way have inferior swelling and aging properties owing to dehydrofluorination during cross-linking, which leads primarily to a decrease of the fluorine content. The diene structures thus formed can then undergo undesirable reactions (e.g., they catalyze further HF elimination in the presence of base), which can lead to uncontrolled formation of new cross-linking bridges and oxidative degradation, and finally to loss of the good mechanical properties.

Reactive groups are introduced to circumvent these problems, for example to improve the resistance to automotive lubricating oils and aqueous fluids, and, in addition, to enable the vulcanization of more highly fluorinated and even perfluorinated rubbers. For the commercial fluororubber grades, that are cross-linkable with peroxides (radically), bromine or iodine (or both) can be introduced into the polymer chain. This is performed either through *copolymerization with bromine-containing monomers* [121], [122], [140-142] (in the simplest case with bromotrifluoroethylene) or by using compounds that contain iodine, or iodine and bromine, as chain-transfer agents [143-146]. Cross-linking occurs above 150 °C by using suitable peroxides [e.g., 2,5-bis(*tert*-butylperoxy)-2,5-dimethylhexane]. Di- or trifunctional olefins are added as co-cross-linking agents, of which triallyl isocyanurate forms the most stable cross-linking bridges [140].

Improved vulcanizate properties (in particular, increased stability toward bases) are counterbalanced by processing problems. Severe mold contamination and the formation of toxic vulcanization cleavage products, such as methyl bromide, are particularly undesirable [125], [129]. More recent developments are aimed at obtaining peroxide-vulcanizable rubbers with optimal processing behavior (low mold fouling) and good vulcanizate characteristics (mechanical and aging properties), by combination of copolymerization with a bromine-containing comonomer and termination with iodine compounds [147, 150, 151].

Other reactive groups, which form cross-linking bridges with correspondingly high termal stability, were developed specially for *perfluoroelastomers*, whose maximum service temperatures reach 280 °C [121], [122]. Perfluoro(vinyl ether) monomers with terminal cyano or perfluorophenyl groups in the saturated side chain are used as reactive groups. They form cross-linking bridges as follows:

Vulcanized molded articles from perfluoroelastomers are made by Du Pont for special applications (trade name Kalrez). The nature of the reactive group depends on the conditions of use, because differing resistances to heat and chemicals are achieved depending on the type of cross-linking [122].

Production of vulcanizates involves first mixing raw rubbers with low-activity fillers, acid scavengers, and the corresponding co-cross-linking agents and catalysts, depending on the type of cross-linking. Molding and cross-linking are carried out between 160 and 200 °C. For 100 % vulcanization and removal of volatile substances the vulcanizate is then generally tempered for 24 h at > 200 °C.

Recent developments are focused on the improvement of mold flow properties and the optimization of cure characteristics (scorch safety, faster cure rate) in order to produce grades that are better processable in extrusion and injection molding [152], [153].

2.6.3. *Production Processes*

The starting materials for almost all fluoromonomers are hydrochlorofluorocarbons and hydrofluorocarbons, e.g.

$$CHClF_2 \rightarrow TFE, HFP + HCl$$

$$CH_3 - CClF_2 \rightarrow VDF + HCl$$

The most common fluororubbers are produced by radical emulsion polymerization at 5 to > 60 bar and up to 120 °C [121], [148].

Processes for production of vinylidene fluoride copolymers by solution polymerization have also been described [149]. However, they do not appear to be very practicable because of the limited choice of suitable solvents (only alkyl acetates or formates) and the high tendency of almost all organic solvents to transfer hydrogen to the reactive growing fluoropolymer radical. Thus, polymerization is stopped at an early stage, and no high molar mass products are obtained.

For formation and *stabilization* of the emulsions, fluorinated emulsifiers are necessary. Generally these are perfluorinated C_6– C_{10} carboxylates or sulfonates, the ammonium salt of perfluorooctanoic acid being the most frequently used. The use of microemulsions formed by a perfluoropolyoxyalkylene and water is recommended for a smooth introduction of special monomers, such as perfluoroalkyl vinyl ether and/or ethylene, into the copolymer [154]. Water-soluble inorganic peroxides commonly used in emulsion polymerization, such as ammonium or potassium peroxodisulfate, are used as *initiators.* The production of tetrafluoroethylene – propene copolymers is performed at low temperature because the transfer of allyl hydrogen at high temperature leads to retardation and insufficiently high molar masses. Therefore redox systems must be used as initiators only in these cases. *Chain-transfer agents* are used to regulate the molar mass. A wide choice of these is available because of the high radical reactivity already mentioned. Commonly used chain-transfer agents are isopropanol and diethyl malonate. The molar mass is generally not regulated by varying the quantity of initiator, because this leads to an increased content of ionic terminal groups and impairs the processing properties of the rubber.

Since fluororubbers are often composed of monomers with differing reactivities, the monomer concentrations during polymerization must be kept constant to obtain chemically uniform products. For this reason, continuous or batch processes are used exclusively. Continuous polymerization is carried out in a stirred-tank reactor with approximately ideal mixing under steady-state conditions. Water is charged together with initiator, emulsifier, buffer, chain-transfer agent and other additives, and the monomers, and the resulting emulsion is discharged continuously. Vinylidene fluoride copolymers are generally produced by using short residence times (15 min), constant temperatures between 90 and 120 °C, and pressures between 50 and 60 bar. Charge and discharge are adjusted in such a way that conversions of > 90 % are achieved. Further steps, such as monomer recycling, coagulation, washing, and drying, are performed according to the standard techniques used for emulsion rubbers.

2.6.4. *Producers, Production, Capacities, and Markets*

During the last decade fluororubber consumption increased from about 7000 t in 1988 to a 1997 demand of 15 000 – 20 000 t, divided among the following regions: 33 % EU, 40 % NAFTA (United States, Canada, Mexico), and 23 % Japan/South Korea (rest of the world 3 %). In 1993 worldwide production capacities were 22 000 t, essentially divided among five producers. The two major producers have strengthened their position by forming joint ventures: The Du Pont–Dow Elastomers joint venture is the largest producer, selling its rubbers under the trade name Viton. The second largest producer is Dyneon, a joint venture consisting of the 3M fluoroelastomer division and the fluoropolymer division of Hoechst (trade name: Fluorel). Other suppliers are Ausimont–Montefluos (trade name: Tecnoflon), Daikin Kogyo (trade name: Daiel), and Asahi Glass (trade name: Aflas).

3. Solution Rubbers

Heinz-Dieter Brandt, Wolfgang Nentwig, Nicola Rooney, Ronald T. LaFlair, Ute U. Wolf, John Duffy, Judit E. Puskas

3.1. Synthesis by Anionic Polymerization

3.1.1. *Solution 1,3-Butadiene – Styrene Rubber (S-SBR) and Styrene – Isoprene – Butadiene Rubber (S-SIBR)*

3.1.1.1. *Properties, Grades, and Applications*

Copolymers of styrene and 1,3-butadiene (SBR) are elastomers of great technical importance that are used predominantly in automobile tires [157]. Copolymerization can be performed either in a free radical emulsion process (E-SBR; see Section Emulsion Styrene – Butadiene Rubber (E-SBR)) or in a solution process by anionic initiation (S-SBR). The emulsion process yields pure random copolymers with a fixed microstructure of the incorporated butadiene moieties. The solution process is more versatile: the microstructure of the butadiene moieties and the styrene sequence distribution (pure

random to true block copolymers) can be adjusted [158], [159]. In addition, a great variety of endgroups can be incorporated by using the solution process [159].

S-SBR with a *random styrene sequence distribution* is predominantly used for standard rubber applications, whereas styrene – butadiene block copolymers are used in plastics applications such as high impact polystyrene (HIPS) and acrylonitrile – butadiene styrene terpolymer (ABS) (see also ⟶ Polystyrene and Styrene Copolymers).

Random Styrene – Butadiene Copolymers (S-SBR). The main application area of S-SBR is in passenger car tire treads, although E-SBR is still predominantly used in this field. However, with investigations focusing on improvements in wet grip (higher safety) as well as rolling resistance (lower fuel consumption) and abrasion resistance, the consumption of S-SBR has been increasing [157]. The proportion of energy loss ratio via the tire tread accounts for 40 % of the energy losses brought about by the whole tire [160], [155]. Therefore, the reduction of the energy loss due to tire tread is the most effective way to lower the rolling resistance. However, any improvement in rolling resistance is normally combined with a deterioration of wet grip performance (wet skid resistance). Elastomers with a low T_g show very low rolling resistance but poor wet grip performance, while elastomers with a high T_g have a good wet grip performance in combination with high rolling resistance [156, 161, 162]. Figure 9 shows the trade-off relationship between rolling and wet skid resistance.

Figure 9. Trade-off relationship between rolling resistance and wet skid resistance for tire tread rubbers [163]

Many investigations to optimize the balance between high wet grip and low rolling resistance in combination with high wear performance are based on S-SBR. Typical polymer and vulcanizate properties of E-SBR and S-SBR are compared in Table 15. Because of its broad molar mass distribution and its high degree of branching E-SBR can be processed more easily than S-SBR. S-SBR cures faster than E-SBR. However, E-SBR has a higher tensile and tear strength than S-SBR. S-SBR shows lower hysteresis and provides a higher modulus. Moreover, the green strength of S-SBR is significantly improved in comparison to E-SBR.

Table 15. Polymer and vulcanizate properties of E-SBR and S-SBR

Property	S-SBR	E-SBR

* M_w = mass-average molar mass; M_n = number-average molar mass.

E-SBR and S-SBR also differ in hydrocarbon content. E-SBR contains only ca. 90 % hydrocarbon due to the high level of soap residue (see Section Basic Chemistry and Production Processes), while the hydrocarbon content of S-SBR is close to 100 %. These soap residues are responsible for the high

hysteresis of E-SBR [164]. However, these residues also improve the processibility and increase tear strength.

Due to the difference in microstructure [different content of 1,2-(vinyl)-configurations], standard S-SBR has a lower T_g than E-SBR at the same level of bound styrene (Table 15). Also the difference in macrostructure is obvious. S-SBR has a narrower molar mass distribution and a more linear backbone.In tire tread applications S-SBR therefore provides lower rolling resistance, improved dry slide traction, and superior wear resistance, while E-SBR provides the better wet slide traction [165], [166].

In 1991 the "green tire" concept was launched with Michelin's patent application [339]. In this concept, the subsitution of silica for carbon black gives rise to lower rolling resistance, improved wet grip, and good wear properties. In terms of rubber, this concept is based on S-SBR or blends of S-SBR with BR or NR: An strong increase in the demand for "green tires" is anticipated [180].

Vinyl-S-SBR (VS-SBR). Traditional S-SBR types with 10 % vinyl content are of minor interest for use in modern high performance tires [157]. S-SBR grades with a vinyl content up to 70 % and with a styrene content up to 40 % are tailor-made for this application and are commercially available. They meet the demand for lower rolling resistance and higher wet grip. By additional variation of the macrostructure (bimodal molar mass distribution), the aforementioned effects are enhanced and, furthermore, the processibility is improved [170-172].

Styrene – Isoprene – Butadiene Terpolymer (S-SIBR). The development of S-SIBR is based on the "wide modal tan δ concept" [173]. S-SIBR rubber is often referred to as *integral rubber*. It has a tailor-made chain consisting of different segments exhibiting different T_gs. The maxima of the damping peaks of the separate segments result in a tan δ curve of the polymer with a wider peak profile. The principle is shown in Figure 10. The absolute values for tan δ given for the three temperature ranges in Figure 10 indicate the generally accepted relationship between tan δ and tire characteristics regarding rolling resistance (50 to 80 °C), wet grip (– 20 to 20 °C), and wear resistance (– 50 to – 100 °C). This concept has been known for several years [174-176, 179]. Commercial production of S-SIBR began in the United States in 1991 [157].

Figure 10. "Integral rubber"—wide modal tan δ concept [173]

Improvements in the manufacture process were reported in the 1990s [180], [181]. The concept of chain-end coupling can be applied also with S-SIBR [182]. Tire tread compounds containing S-SIBR and silica as filler are claimed to have improved properties [183].

Styrene – Butadiene Block Copolymers. These block copolymers exhibit two separate ranges of T_gs: – 80 to – 90 °C for the polybutadiene block and 70 to 80 °C for the polystyrene block [184]. These polymers are not suitable for standard rubber applications such as tires [162].

Butadiene – Styrene Diblock Copolymers (SB). SB diblock copolymers are used for the production of HIPS and mass polymerized ABS, either alone or in blends with polybutadiene. By using diblock copolymers, HIPS properties such as gloss and transparency which are often unsatisfactory can be improved [185], [186]. SB diblock copolymers can also be used to increase impact strength of polystyrene and polyolefins by mechanical blending.

SB diblock copolymers with different styrene content are available: 40 % bound styrene (for HIPS), 30 % bound styrene (for ABS, HIPS), 25 % bound styrene (for carpet pads and bitumen modification), and 10 % bound styrene (for ABS).

Styrene – Butadiene Triblock Copolymers (SBS). Linear [187] and radial SBS types [188], [189] are commercially available. They are typical thermoplastic elastomers (see Section Styrene Block Copolymers; ⟶ Thermoplastic Elastomers).

3.1.1.2. *Basic Chemistry and Production Processes*

The versatility of anionic solution polymerization allows the formation of tailor-made diene – styrene copolymers. The unique features of copolymerization initiated by butyllithium in nonpolar hydrocarbon solvents are:

1. Absence of spontaneous chain terminations (living chains polymerization, ⟶ Plastics, General Survey – Anionic Polymerizations), which allows the sequential addition of monomers and the use of chain-coupling techniques
2. Absence of chain-transfer reactions to give essentially linear and gel-free polymers
3. A wide choice of chain microstructures [159], [190], [194]

The use of butyllithium in nonpolar, hydrocarbon solvents leads to polybutadienes in which the diene units are present mainly in the 1,4-configuration (ca. 90 %), the remainder being in the 1,2-configuration (vinyl structure).

SB Diblock Copolymers. SB copolymers are usually produced in a batch polymerization. Because of the different reaction rates of the two monomers in hydrocarbon solvents (reaction rate of butadiene is higher), the diene dominates the initial copolymerization reaction. This inevitably leads to the formation of tapered diblock copolymers in which the almost pure polybutadiene block is connected to a polystyrene block through a transitionally random polymer segment consisting of increasing proportions of styrene. About 75 % of the total bound styrene content is incorporated as a polystyrene block [158], [195].

SBS Triblock Copolymers (SBS). Different strategies exist for the synthesis of triblock styrene – butadiene copolymers:

Due to the "living character" of the anionic polymerization, SBS can be produced by polymerization of styrene to form *living polystyrene chains*, followed by chain extension with butadiene to form a diblock (SB) which then can be (1) extended with a second polystyrene end-block [187] or (2) coupled with di- or polyfunctional coupling agents (e.g., mono- or diesters, metal halides) to produce linear, 3-, 4- or multibranched copolymers [189].

Triblock copolymers can also be produced by dilithium compound-initiated polymerization of butadiene to form *living polybutadiene chains* followed by building the styrene blocks on both ends of the polybutadiene chain by adding styrene [196], [197].

S-SBR. Completely random copolymers can be obtained in nonpolar solvents either by a continuous polymerization process [198] or a semibatch process with programmed addition of butadiene to the reaction mixture [199]. S-SBR made by these routes is characterized by a vinyl content of ca. 10 % in the diene fraction.

Another route utilizes randomizers, in batch or continuous operation. These randomizers or modifiers are polar compounds such as ethers or amines which decrease the difference between the reactivities of butadiene and styrene to such an extent that both monomers are consumed at virtually equal rates [200], [201]. The randomizing action of these polar compounds results from an effect they have on the initiator and coincides with an increased amount of

1,2-addition in butadiene polymerization. The vinyl content in the polybutadiene depends on the modifier type, modifier – catalyst ratio and concentration (modifier and catalyst), and the polymerization temperature [161]. The vinyl content of the diene fraction can be up to 90 %.

This process flexibility is an important and attractive possibility — in addition to changing the bound styrene level — to control the T_g of the derived polymers. The relationship between the vinyl and styrene contents and T_g is illustrated in Figure 11 for a series of random S-SBR. The high linearity together with a narrow molar mass distribution of the S-SBR results in a relatively poor processing performance during mixing and molding operations. This can be improved by the coupling of polymer chains through the "living" chain ends. Various coupling agents (dihalides, tetrahalides, divinylbenzene, etc.) are available [170-172], [202]. Tin tetrachloride shows not only good coupling efficiency but also an improved interaction (e.g., better rolling resistance) with the filler carbon black. A similar effect can be obtained by a chain end modification by terminating the "living" chain end with a modifier such as *N*-methyl-2-pyrrolidone [203], *N*-substituted aziridines [204], aminobenzophenone compounds [177], [178], and substituted imines [205].

Figure 11. Relationship of T_g to bound styrene and vinyl content [156]

The concept of introducing polymer-bound functionalities can be extended by using functionalized initiators such as lithium cycloalkylamides [191-193], lithium compounds containing imine groups [213], [214], and LiSn alkyls [216], [217].

Novel S-SBR types formed by selective hydrogenation of 1,2-vinyl units have been presented. They are characterized by an extremely small hysteresis loss at high temperature and a large loss at lower temperature [218].

Process Description. S-SBR, VS-SBR, and S-SIBR are commercially produced by batch and continuous anionic solution processes. Typically, these processes consist of four operating stages: polymerization, monomer and solvent recycling, product recovery, and product finishing. The polymerization is carried out at 50 – 100 °C and 1 – 5 bar in a batch reactor or in a reactor train of two to four stirred-tank reactors. Conversion is complete after a residence time of ca. 1 – 4 h depending on the temperature, monomer concentration, catalyst, and modifier levels. Immediately downstream of the reactor, the polymerization is terminated with alcohol or other polar liquids. After the addition of stabilizers and, depending on the polymer type, extender oils, the polymer solution is coagulated and stripped with steam and hot water to remove unreacted monomers and solvents. The rubber crumb is then passed over a screen to remove free water and subsequently dried. Either extrusion or hot air drying may be used. S-SBR, VS-SBR, and SB are sold in the form of bales.

3.1.1.3. *Producers and Production Capacities*

The commercial production of S-SBR started around 1965. The *consumption* increased from 400 000 t in 1980 (16 % of total SBR market) to 440 000 t in 1991 (15 % of total SBR market).

The *production capacity* was ca. 610 000 t in 1996. The S-SBR plant capacity is, in almost all cases, part of a multipurpose anionic solution polymerization facility. Thus, if the demand for S-SBR increases in the future, parts of the multipurpose plants can be used for S-SBR production. Table 16 gives an overview of the S-SBR producers, their S-SBR capacities in 1992, and the capacities of their multipurpose facilities [206].

3.1.2. *Lithium – Butadiene (Li-BR) and Lithium – Isoprene (Li-IR) Rubber*

3.1.2.1. *Properties, Grades, and Applications*

Polybutadiene. produced with lithium initiators is often described as a low- or medium-*cis*-1,4-polymer. When produced in an aliphatic, cycloaliphatic, or aromatic solvent, a polymer of ca. 36 – 38 % *cis*-1,4-, 52 % *trans*-1,4-, and 10 % 1,2-content is produced. The 1,2-content of the polymer can be varied over the range from 10 to 90 % by the addition of polar additives. The higher the 1,2-content, the higher is the T_g of the polymer. Standard lithium polybutadiene of 10 % vinyl (i.e., 1,2-)content has a T_g of – 93 °C, whereas the T_g of a 90 % vinyl polymer can be expected to be ca. – 20 °C [207], [208].

A considerable amount of lithium-initiated polybutadiene is used to produce *high-impact polystyrene* (HIPS) (⟶ Polystyrene and Styrene Copolymers – Polystyrene) [209]. BR is the rubber of choice because it dissolves readily in styrene and gives rubber domains of the appropriate size that inhibit crack propagation. BR is the most efficient impact modifier for polystyrene on the basis of impact improvement relative to rubber level used. Lithium polybutadiene is used in this application because it can be produced with uniformity and high purity. It competes in this application with cobalt polybutadiene produced by Ziegler – Natta catalysis (see Section Polybutadiene and Polyisoprene Rubber). The viscosity of the rubber solution in styrene is important to the HIPS producer. The solution viscosity of the rubber in styrene is a function of the molar mass, molar mass distribution, and branching of the polymer. Various proceses can be used to branch lithium polymers. Small amounts of divinylbenzene (DVB) may be added or the branching process may be carried out thermally. Branching also helps in handling the rubber because linear polymers are very prone to cold flow. Levels of gel in the polymer must be ≤ 200 ppm. A higher 1,2-content of the lithium polymer (10 %) causes faster grafting than that observed with cobalt polymers with a 1,2-content of only 2 %. Because of this the HIPS process must be adjusted to the polymer in use.

Some lithium polybutadiene grades have been used in *tires*, but the production volume of these grades is relatively small. The standard lithium polymer exhibits poor processing behavior and does not give the excellent tread wear that is typical of the high-*cis*-polybutadienes made by Ziegler – Natta polymerization [210]. More recent work to produce lithium polybutadienes for improving tire performance, however, has been relatively successful. Lithium chemistry allows the production of polymers with very specific molecular architecture (branching, end groups, microstructure, copolymerization control, etc.). Specific lithium polybutadiene polymers and solution SBR polymers are now being made to meet the increasing demands of tire manufacturers [211]. Lithium polymers with high vinyl content are used in winter tires and tires with lower rolling resistance.

Specific polar end groups are sometimes added to improve the bonding of the polymer to carbon black. Branched and coupled polymers are made to improve processing and to alter the dynamic properties of the tire. Star-branched lithium polymers are used in very highly carbon black-loaded compounds, such as bead or chafer compounds, because they can easily be compounded with large amounts of carbon black. Copolymers with styrene and, in some cases, isoprene further extend the range of special products available to tire designers. To date, the market volume of such materials is not large (see Section Solution 1,3-Butadiene – Styrene Rubber (S-SBR) and Styrene – Isoprene – Butadiene Rubber (S-SIBR)), but growth of these materials is expected. Functional lithium initiators with an end group that can bond to carbon black are now being studied to further improve rolling resistance.

Lithium polyisoprene. is produced on a small scale for use as a processing aid for natural rubber and in other applications where its high purity is an asset. A tread specialty polyisoprene with a high 3,4-content is also produced, as well as a liquid IR.

3.1.2.2. *Basic Chemistry and Production Processes [212], [226]*

Lithium Polybutadiene. Anionic polymerization offers many possibilities for synthesizing tailor-made polymers. Only the most important aspects of lithium chemistry are covered here. For a broader understanding of the many complex products which can be made using lithium chemistry, see [220]. Polymerization of dienes such as butadiene and isoprene can be initiated by alkali metals or organoalkali compounds. The use of organolithium initiators is advantageous because of their solubility in polar and nonpolar solvents. In the case of *organolithium initiators* (e.g., butyllithium), the initiation step can be regarded as a nucleophilic attack of the initiator on the monomer, generating an allylic organolithium compound, which is able to add the next monomer molecule. Further addition of monomer leads to polybutadiene or polyisoprene chains, which still possess an organolithium unit at the end. Depending on the nature of the solvent and other reaction conditions, the carbon – lithium bond has a more or less ionic character. In sufficiently pure systems at moderate temperature, transfer and termination reactions do not occur to a significant extent. Therefore, the active species retain their reactivity, and the polymerization is often described as living (⟶ Plastics, General Survey – Anionic Polymerizations). In pure systems the polymerizations go to completion. The molar mass of the product can be calculated from the number of moles of monomer divided by the number of moles of butyl lithium. The product has a narrow Poisson distribution, if the initiation is rapid and side reactions are avoided.In the ideal case, the polymer chains are linear. The narrow molar mass distribution and high linearity usually yield polybutadienes that are difficult to process. Thus, introduction of branches or broadening the molar mass distribution can be useful.

Copolymerization of butadiene with small amounts of a branching comonomer such as divinylbenzene yields products that are easier to process and have a reduced cold flow. Partial or quantitative coupling of polymer chain ends [227] can also be used. Common coupling agents are metal halides, such as $SnCl_4$ and $SiCl_4$, or diesters. Moreover, anionic polymerization offers the possibility of using multifunctional initiators and introducing functional groups at the chain end during termination [226], [228]. Of the many functional end groups which can be used to terminate the polymer, two main types have been used to improve tire properties. The use of tin compounds in any form (R_3SnCl, R_2SnCl_2, $RSnCl_3$, or $SnCl_4$) leads to a tin-containing group in the molecule which improves the bonding of the rubber to carbon black [221], [222]. Depending on the number of chlorine atoms in the tin compound, these materials can also introduce branching of the polymer and alter processing characteristics Another class of compounds used commercially to introduce end groups are benzophenone derivatives such as *bis*(4,4'-diethylamino) benzophenone [223]. Many other end groups have been described in the patent literature to be useful for reduction of rolling resistance.

The success at improving rolling resistance by terminal functional groups has prompted considerable research to incorporated similar groups at the initiation end of the molecule [224].

In batch polymerization with a rapid initiator such as *sec*-butyllithium, narrow molar mass distributions can be obtained. In some tire applications bimodel molar mass distributions are desirable. This can be achieved by coupling some of the polymer with, e.g., $SnCl_4$ or $SiCl_4$. To this end, a substoichiometric amount of coupling agents is added, so that some of the polymer is left uncoupled.

In many applications, Li-Br with a narrow molar mass distribution is not needed. Products for these markets are thus often made in a simple continuous process with high polymerization temperature and hexane as the solvent, which results in a broader molar mass distribution.

The *kinetics* of the initiation as well as of the propagation reactions show a first-order rate dependence on monomer concentration that is independent of the solvent used [212], whereas various reaction orders are found with respect to the initiator concentration, depending on solvent type and other parameters. This is a consequence of the different nature of the initiator, the propagating chain end, and the mechanism under different reaction conditions. In nonpolar solvents, the growing polydienyllithium molecules associate in pairs, whereas the addition of polar solvents such as tetrahydrofuran results in partial dissociation of the pairs, and stabilization of the ionic bond by solvation of the lithium ion, leading to charge separation. In addition to the effect of kinetics, the microstructure is strongly affected by the nature of the propagating chain end, by solvation and association, and by the polarity of the alkyl – metal bond; therefore changing the alkali metal in the initiator drastically changes the microstructure. In *nonpolar media*, Li-BR with ca. 90 % 1,4-units is obtained and the *cis* : *trans* ratio increases with decreasing initiator concentration. Temperature does not strongly affect microstructure in nonpolar media. Conventional Li-BR has about 33 – 38 % *cis* content [229] and is therefore called low-*cis*-BR [207]. The content of 1,2-units in the polybutadiene chain is increased by the addition of *polar modifiers*; the level is influenced by the amount and type of polar modifier used and by the polymerization temperature [227]. Considerable attention is needed for the selection of a suitable polar modifier. Some modifiers give rise to side reactions which may prohibit coupling or addition of functional end groups. Amount and cost of the polar modfier may be important, especially if the polymeriization temperature or the desired vinyl level is high. Both conditions necessitate addition of higher levels of modifier. Being polar molecules, modiifiers are of concern as regards hygiene and pollution and may pose problems in solvent reprocessing systems.

Lithium-Polyisoprene. The basic chemistry in anionic polymerization of isoprene via alkyllithium initiation does not differ much from that of butadiene. Since isoprene can be regarded as a butadiene that is methyl substituted in the 2-position, the 1,2- and 3,4-addition products are not identical. Consequently, four different units can exist in the polymer chain. In nonpolar media or with no solvent, very high *cis*-1,4-content is attainable by alkyllithium initiation (e.g., 96 % *cis*-1,4- and 4 % 3,4-units with no solvent and with low concentrations of *sec*-butyllithium). The presence of solvent or an increased initiator concentration can decrease the *cis* and increase the *trans* content [230]. By the addition of polar solvents, polyisoprene with mainly 3,4-units and possibly some 1,2-units can be synthesized [212]. Commercial “low-*cis*” polyisoprene has a *cis* content of ca. 92 % [207] in contrast to the Ziegler – Natta

IR types with higher *cis* content.

Process Description. (see Fig. 12). A typical process for the production of lithium polybutadiene is shown in Figure 12. The polymerization can be carried out in a broad range of aliphatic, cycloaliphatic, or aromatic solvents. The solvent system is chosen to have a solubility parameter appropriate to the polymer. Especially when styrene copolymers are to be made in the same plant, the solubility parameter of the solvent must be sufficiently high to keep the polymer in solution. Simple Li-Br is usually made in mixed hexane isomers, however, in plants where SBR or block copolymers are also produced, it may be necessary to improve the solubility parameters by adding other better solvents such as cyclohexane. Because of the sensitivity of the system to polar impurities, the monomer and solvent streams must be very pure. The feed is typically dried by azeotropic distillations (a) to lower the water content to a few parts per million. The polymerization (b) itself is quite straightforward. The butyllithium initiator is added to the reaction mixture, and polymerization occurs usually going to completion. Different reactor configurations can be used to produce either narrow or broad molar mass distributions as desired, and DVB may be added to increase branching of the polymer.

One of the advantages of lithium chemistry is the ability to polymerize at relatively high temperature where water cooling is adequate and reactions are rapid.

For HIPS application a colorless polymer with a good stability, and a gel level < 200 ppm is required. This means that the polymer must be well protected during the production process. Tradionally, a combination of a hindered phenol as a free radical scavenger and a phosphite as hydroperoxide decomposer has been used as antioxidant. Concerns about the deleterious effects of nonylphenol produced by hydrolysis of trinonylphenyl phosphite has led to the search for new antioxidant systems.

The need for a low gel content requires that the drying and finishing steps be carried out without excessive shear or temperature increase. Effective processes for shortstopping and for extraction of lithium residues are also required, because residues left in the rubber will lead to gel and color formation.

Removal of the solvent and any residual monomer is carried out by contacting the dissolved rubber with steam and water (c). The hydrocarbon is stripped off, and small rubber particles remain suspended in the water. Further contact with steam reduces the content of hydrocarbon in the rubber. Improvement of the stripping process has been necessary because of the need to reduce the pollution of air and water; this has been accomplished with better contactors and additional stripping vessels. The slurry of rubber is then dewatered (d), usually with an extruder that squeezes out most of the water. A final drying stage in a fluidized bed or tunnel dryer (e) completes the process, and the rubber is baled and packaged (f).

Earlier processes for removing solvent directly with drum dryers have now largely been abandoned. A thin layer of polymer cement was dried on a large heated drum but this process is no longer used extensively because of the inherently high solvent losses.

3.1.2.3. *Producers and Production Capacities [229], [231]*

Polybutadiene rubber. is the second largest synthetic rubber product after SBR: In 1995, 1 402 000 t was produced, exclusive of Eastern Europe and the socialist countries of Asia. Worldwide annual BR capacities were about 2 3280 000 t at the end of 1996, as estimated by the International Institute of Synthetic Rubber Producers. This figure is, however, difficult to interpret, because most of the capacity can be used to produce BR, SBR, and block copolymers. Special BR types — e.g., polymers with special end groups, liquid polymers, high-vinyl polymers — are produced only in small amounts.

The technology for the preparation of Li-BR was developed by Firestone Tire & Rubber Co. [208], [232] in the 1950s; Firestone is still proucing Li-BR with the trade name Diene. Among the other producers of low- and medium-*cis*-BR, and in some cases of high-vinyl types as well, are the following producers listed in Table 17 (with trade names).

Table 17. Producers of polybutadiene rubber

Company	Country	Trade name
Asahi Chemical	Japan	Asadene
Bayer	France	Buna
Bayer	United States	Taktene 550
Coperbo	Brazil	Coperflex BR
Enichem	Italy	Intene, Intolene
Firestone	United States	Diene
Japan Elastomer	Japan	Asaprene
Karbochem	South Africa	Afdene
Kumho	Korea	
Negromex	Mexico	Solprene
Petrochim	Belgium	Finaprene
Repsol	Spain	Calpene

Isoprene Rubber. According to IISRP statistics, 116 000 t of synthetic isoprene were produced in 1995 outside the Eastern bloc countries. Most of this is high-*cis* material produced by Ziegler – Natta catalysts. Shell Nederland Chemie produces Li-IR under the trade name Cariflex [233]. A 3,4-polyisoprene previously produced by Hüls (Vestogrip) is now made by Karbochem under the trade name Isogrip. Kurarary produces a small amount of liquid IR.

3.2. Synthesis by Ziegler – Natta Polymerization

3.2.1. *Polybutadiene and Polyisoprene Rubber*

3.2.1.1. *Properties, Grades, and Applications*

High-cis-Polybutadiene. High-*cis*-polybutadiene is the second largest volume synthetic elastomer, second only to emulsion SBR: It is used primarily in the manufacture of tires. Moderate amounts are also used in high-impact polystyrene and ABS. In these markets it competes with lithium polybutadiene (see Section Lithium – Butadiene (Li-BR) and Lithium – Isoprene (Li-IR) Rubber). Small amounts of high-*cis*-polybutadiene (2 – 3 %) are used in other applications, such as golf balls, hose roll covers, and conveyor belts.

The principal characteristic of this polymer is the high content of *cis*-1,4-microstructures, which is generally 92 – 98 % (Table 18). The *cis*-1,4-polymer chain has a very low T_g (– 10 °C). This leads to high resilience, good low-temperature properties, and low heat buildup on repeated deformation [238-240]. These characteristics are needed in tire treads, carcass stocks, and sidewalls [241]. High *cis*-BR provides the extremely rapid chain motions needed for abrasion resistance and resilience of tires. In the tread portion of the tire, *cis*-BR is blended with rubbers with a higher T_g, such as SBR, to improve traction.

The differences in microstructure shown in Table 18 do not decisively affect product performance. The vinyl group has a higher T_g (≈ – 106 °C), but since

the vinyl content is only 0 – 4 %, it has only a small effect on the overall glass transition temperature. The higher level of *cis*-1,4-microstructure seen when neodymium is used as catalyst seems to improve fatigue properties in some applications. The higher linearity of Nd-Br polymers may also contribute to this result.

Table 18. Dependence of microstructure of Ziegler – Natta polybutadiene on catalyst used

	Cis content, %	*Trans* content, %	Vinyl content, %	Molar mass distribution	T_g, °C
Cobalt	97	1	2	moderate	– 106
Titanium	93	3	4	moderate	– 103
Nickel	97	2	1	broad	– 107
Neodymium	98	1	1	very broad	– 109

High *cis*-BR polymers show significant variation in processing characterstics because of differences in molar mass, molar mass distribution, and degree of branching. These factors vary even within polymers produced by the same catalyst system, so overall conclusions about preferred catalyst systems are somewhat difficult to reach. On balance, the *nickel-catalyzed* polymers, with their broad molar mass distribution and slightly higher degree of branching are somewhat easier to process (better mill compound behavior and extrudability), but their tensile properties and fatigue resistance are inferior. *Titanium-catalyzed* polymers, with their lower branching and moderate molar mass distribution, are more difficult to process but better in tensile strength and fatigue resistance. Polymers synthesized with *cobalt catalyst systems* can be produced with a varying degree of branching. The branched grades are easy to process, whereas the more linear polymers have better dynamic mechanical properties. Polymers made with *neodymium systems* are highly linear and have a broad molar mass distribution. This gives them a desirable balance of properties with the exception of poor extrudability and high cold flow. The processing properties of some neodymium-catalyzed polymers are improved by “molar mass jumping” as described below.

Most high-*cis*-BRs do not have the high tack and green strength of natural rubber. When the products were developed, extensive work was carried out to determine the reasons for this and to improve the product, but a commercially attractive route does not seem to have been found. Polymers produced with neodymium systems are somewhat improved in this regard, but still not to the level of natural rubber.

High-*cis*-BR is also prone to cold flow (i.e., the tendency of unvulcanized rubber to flow during storage). In extreme cases, the bales of high-*cis*-butadiene rubber are completely distorted to the point that the film wrap splits. Cold flow is most serious for low molar mass or highly linear materials. Long-chain branching is introduced into some products to reduce cold flow. This can be carried out by postpolymerization reactions, sometimes termed “molar mass jumping”, that involve reacting the polymer in solution with disulfur dichloride.

As noted above, high-*cis*-BR has relatively poor processing properties. In many cases, this is due to stress relaxation, which is too fast. Slower relaxations as a result of branching or molar mass jumping improves processing on mills. Processing problems with high *cis*-polymer are diminished in compounds of higher *cis*-BR where either SBR or natural rubber is also present.

As with all polymers, mechanical properties are a function of molar mass. Tensile strength, abrasion resistance, and fatigue resistance all improve as the molar mass of the polymer increases. Balanced against this, of course, is the greater difficulty of mixing and processing higher molar mass polymers.

Oil extension with naphthenic or aromatic oil is used to make higher molar mass products processible. One producer of high-*cis*-BR also makes a polybutadiene black masterbatch. In this case, both carbon black and oil are added to the polymer while it is still in solution. This facilitates subsequent processing and allows high molar mass polymers to be handled with relative ease.

As mentioned previously, the degree of branching of these polymers can vary. Relatively little is known about the nature of this branching or about its cause. However, the branching differences in the products can be observed fairly easily in dynamic mechanical or stress relaxation tests.

Another important characteristic of some grades of polybutadiene is the gel content. In tire applications this is not generally a concern. However, BR used in high-impact polystyrene must have very low gel levels. It is primarily the cobalt-catalyzed BR that is used to produce HIPS (the other product used is lithium-catalyzed BR; see Section Lithium – Butadiene (Li-BR) and Lithium – Isoprene (Li-IR) Rubber). The neodymium catalyst system may be capable of producing HIPS-quality BR, but unsatisfactory control of solution viscosity has so far kept it out of this application.

In addition to the low gel content, HIPS-BR must also contain low residues of catalyst, have little color, and contain a suitable type and level of antioxidant so that the HIPS polymerization is not retarded. The most common antioxidant system is a combination of a hindered phenol and a phosphite. Concern about the adverse health effect of free nonylphenol formed by hydrolysis of trinonylphenyl phosphite has led to the evaluation of new stabilizers that do not contain trinonylphenyl phosphite.

Although the content of 1,2-units is only 0 – 4 %, it can still influence the HIPS process by affecting the rate of grafting of the polystyrene on the rubber. The solution viscosity of the rubber in the styrene monomer is also of considerable importance because it determines how, and when, the rubber phase breaks up to yield rubber particles. The size and nature of the rubber particles are very important in determining the impact properties of HIPS (see also ⟶ Polystyrene and Styrene Copolymers – Introduction).

High-cis-Polyisoprene. Polyisoprene produced with a Ziegler – Natta catalyst attracted considerable interest when it was developed and commercialized in the 1960s. The polymer has a microstructure very similar to that of natural rubber, but it has inferior green strength and tack [241], [242]. Considerable research has been carried out to determine why high-*cis* polyisoprene does not duplicate all the properties of natural rubber. Although natural rubber contains almost 100 % *cis*-1,4-structures, the microstructure is not the only important difference between the synthetic and the natural products. Functional groups on the natural product and nonrubber components are also important in influencing green strength, tack, and tensile properties. Unfortunately, the availability and cost of isoprene have remained a problem. Isoprene synthesis is more difficult than that of butadiene, and its purification is also more complicated (⟶ Isoprene – Production). Isoprene containing C_5 streams from cracking operations are used to the extent available. As a result, both the monomer and the polymer are relatively expensive. The availability of natural rubber at reasonable cost has made the synthetic polymers unattractive, and a number of plants in the Western World have been closed. Some high-*cis*-polyisoprene is still produced by Goodyear JSR and Nippon Zeon. It is used where its high purity is an advantage and also as a processing aid for natural rubber. Shell also produces a polyisoprene in the Netherlands using a lithium catalyst.

Substantial volumes of Ziegler – Natta polyisoprene were produced in Eastern Europe. However, most of the production capacity cannot be operated economically and has been shut down. The operation of such facilities depends on natural rubber pricing.

Other Commercial Ziegler – Natta-Catalyzed Polydienes.
Trans-1,4-Polyisoprene. A Ziegler – Natta system is used by Kuraray (Japan) to produce *trans-1,4-polyisoprene* that is similar in molecular structure and properties to the natural product balata. Because of its low melting point the crystalline product can be used for splinting or prosthetic applications. Sheets of the product are softened in an oven or with hot water and then molded to the body and allowed to cool. *Trans*-1,4-polyisoprene is also used for golf ball covers, where it competes with ionomers. The process used to make the *trans* polymer gives a lower yield of product, and the relatively high price of the product limits it to low-volume specialty applications.

Syndiotactic 1,2-Polybutadiene. Another low volume polymer produced by Ziegler – Natta catalysis is syndiotactic 1,2-polybutadiene (JSR BR). This partly crystalline product is a thermoplastic elastomer with high purity. It is produced with only 15 – 30 % crystallinity to make it flexible and processible, and is used as a high-permeability film in food packaging. It is also used as a dispersible film wrap for rubber and rubber chemicals, but in this application it faces stiff competition from much less expensive films, such as polyethylene and ethylene – vinyl acetate copolymer films.

Research on tires is devoted to reduction of rolling resistance without detracting from wear or traction properties. This has resulted in a trend toward S-SBR instead of E-SBR (see Section Emulsion Styrene – Butadiene Rubber (E-SBR)). Tread compounds are also increasingly reinforced with silica instead of carbon black. In the endeavor to improve rolling resistance the levels of high-*cis*-BR in tread compounds were also increased. Some research on novel Ziegler – Natta polymers such as butadiene – isoprene copolymers has been carried out. Thes products have had little commercial success.

3.2.1.2. *Basic Chemistry and Production Processes*

High-cis-Polybutadiene. Ziegler – Natta polybutadiene was first produced by Phillips Petroleum in 1956 using titanium catalysts [243]. This was followed very rapidly by development of cobalt and nickel systems [244-246]. The ability of these catalysts to produce high-*cis* polymers with properties similar to those of natural rubber led to rapid commercialization of both high-*cis*-polybutadiene and high-*cis*-polyisoprene. The latter business dwindled due to the lack of acceptably priced monomer and to competition from relatively low-cost natural rubber. In contrast, the production of polybutadiene has benefited from a ready supply of cheap monomer. Technical developments in the field have been fairly modest since the 1980s, but more recent work on rare-earth catalyst systems has revived interest in product and process improvement. Very good early studies have been carried out by GIPPIN [247], [248]. Reviews of the technology have been published [249-251].

Ziegler – Natta polybutadienes are produced by solution processes using a variety of solvents. Some, such as the titanium process, are best carried out in aromatic solvents, whereas others, such as the neodymium-catalyzed process, can be carried out only in aliphatic or cycloaliphatic solvents. As indicated below, each catalyst system has its own unique features. However, the various Ziegler – Natta systems share common elements. All are sensitive to impurities, thus monomer and recycle solvent streams must be well purified. Carbonyl and acetylenic impurities in the monomer must be at the level of a few parts per million, and the polymerization inhibitor (*tert* butylcatechol) is usually removed from the monomer prior to reaction.

The feed streams of monomer and solvent are usually dried by azeotropic distillation and fed to a series of polymerization reactors. Ziegler – Natta catalysts are, commonly, three-component systems, and both the order of addition and the mixing conditions can be important. The catalyst components may be added directly into the first reactor or some components may be added into a premix vessel ahead of the reactor or into the feed line. Various methods are used to control the molar mass of the products. Molar mass modifiers specific to the catalyst system are used where necessary. The final conversion of ca. 70 – 99 % is achieved in a polymerization time of 2 – 3 h.

After polymerization a short stop is added. Water, fatty acids, or alcohols, can be used to terminate the reaction. Antioxidants are added, and steam and water are brought into contact with the polymer solution to strip off the solvent and any residual monomer. This coagulation and stripping operation leaves the rubber in the form of small particles floating in water. The water is drained off through a screen, and the material is dewatered, usually in an extruder. The final drying is carried out in a fluidized-bed dryer, tunnel dryer, or twin-screw drying extruder.

Good operation of the solvent removal step is important to minimize air and water pollution. Solvent loss of 1 or 2 wt %, based on the weight of polymer, occurred in older processes. Improved stripping conditions, additional stripping vessels, and other changes have been implemented to reduce losses of solvent to ≈ 0.3 wt %. Work has been carried out to improve engineering practices throughout the plants in order to reduce losses at valves, flanges, and pumps. In some cases, air from these sources is ducted and used as boiler combustion air to prevent losses to the environment. There has also been some concern regarding exposure to butadiene monomer, and the improved stripping mentioned above is important in minimizing this exposure.

Co-BR. Polymerization to form high-*cis*-BR, based on cobalt catalysts, was disclosed in early patents to B. F. Goodrich [245], and this technology was later licensed to other companies. Various cobalt compounds can be used. Because $CoCl_2$ is insoluble in the aromatic solvent used, work was carried out to use soluble cobalt salts such as the acetylacetonate, the octoate, or the versatate. These materials are readily available and are easy to handle in solution.

The other catalyst components are an alkylaluminum compound and small amounts of water. Various alkylaluminum compounds can be used. The most common material is diethylaluminum chloride [$(C_2H_5)_2AlCl$], but aluminum compounds containing more chlorine, such as the sesquichloride [$(C_2H_5)_3Al_2Cl_3$], can also be employed. Catalysts with lower chlorine content have reduced activity.

The amount of water used in the system is very important. With *diethylaluminum chloride,* very little polymerization occurs in the absence of water. As the water content is increased, the reaction becomes more rapid, then passes through a maximum, and again declines to zero at higher concentration. As the water level is increased, so does the solution viscosity of the polymer at a given Mooney viscosity. This increased solution viscosity results in improved dynamic properties and is commonly interpreted as a lower degree of branching.

Polymerizations carried out with *alkylaluminum* compounds containing more *chlorine* in the molecule than diethylaluminum chloride can be used without adding water, but in practice, this method generally does not offer any advantages.

Polymerization is usually carried out at 5 – 35 °C, depending on the solvent and the heat removal capability of the reactor. Early work was based mostly on benzene as the solvent. However, with increased concern about loss of solvent to air or water, work has been carried out to find other suitable solvents. Cyclohexane can be used in place of benzene, although side reactions leading to gel formation or to fouling of the reactor may be more pronounced. Aromatic solvents with methyl substituents can be added in small amounts. These substituted aromatics stabilize the catalyst complex but also reduce the reaction rate.

The molar mass of the polymer produced can be controlled by monomer concentration or by the addition of modifiers, such as hydrogen, 1,2-butadiene, propadiene, or cyclooctadiene. α-Olefins, such as ethylene, propene, 1-butene, or 1-hexene can also be used to reduce the molar mass of the polymer.

Cobalt polybutadiene is often used in high-impact polystyrene. HIPS used for extrusion applications must contain less than 200 – 300 ppm of gel to prevent visible defects in the HIPS. To meet such stringent conditions, a catalyst system must be selected that does not favor side reactions, and the feed must be very pure. Extra care is required to keep the product free of gel particles. The polymer solutions are filtered after polymerization, and wash steps are incorporated to remove catalyst residues. Extra care imust be taken to ensure that the product is not degraded.

The reaction rates of cobalt-catalyzed polymerization are generally proportional to the concentrations of both cobalt and monomer. With increasing cobalt concentration the molar mass of the polymer decreases and the polymer becomes more branched.

As mentioned above, the rate of polymerization is a complex function of the amount of water present. The water concentration also influences molar mass, branching, and to a small degree, the microstructure of the resulting polymer. The degree of branching decreases with increasing water level. Gel levels in the product also increase with the amount of water charged. It does not appear, therefore, that gel forms because branching has increased to the point at which a network can form.

Cobalt-catalyzed polymerization is usually carried out with very low levels of cobalt. Many chains are formed by each cobalt atom. In contrast, the alkylaluminum is present in large excess. Water levels in the range of 0.1 – 0.5 mol per mole of alkylaluminum compound are generally used.

The mechanism of polymerization is only partially understood [252]. The functional groups attached to the aluminum and cobalt appear to be exchanged, and cobalt is reduced from Co^{2+} to Co^{+}. Coordination of butadiene to the catalyst complex is involved in the stereoregulating mechanism. When aromatic solvents are present, they can form strong complexes with the catalyst and displace the monomer as a ligand. With substituted aromatics, the catalyst complex can become so stable that little polymerization occurs.

Titanium-Catalyzed Polybutadiene. The Ziegler – Natta polybutadiene process developed by Phillips Petroleum uses a catalyst of titanium tetraiodide and triisobutylaluminum [253]. The low solubility of the titanium tetraiodide in the hydrocarbon solvent led to production difficulties, and numerous other systems were developed to improve handling and product uniformity. The common element in the various systems is the presence of iodine with the eventual formation of a titanium – iodine bond [254-257]. Catalysts that contain other halogens do not yield the desired high content of *cis* microstructure in the polymer and are prone to other difficulties such as the formation of gel and low molar mass oligomers.

A precipitate forms during these polymerizations, which further complicates the process. Extra care must be taken to bring the catalyst species together in a desirable and reproducible way.

Polymerization is usually carried out in benzene or toluene. However, mixed aromatic – aliphatic solvents or even totally aliphatic systems can be used with some difficulty. Polymerization can occur over the range 5 – 50 °C.

The efficiency of titanium catalyst systems is influenced by the aluminum – titanium ratio. The *cis* content, molar mass, molar mass distribution of the product, and catalyst activity are all influenced by this ratio. The optimum ratio depends on the system in use.

Nickel-Catalyzed Polybutadiene. Many Ziegler – Natta catalyst systems, based on nickel, have been disclosed in the literature. Those containing fluorine generally give a high content of *cis*-1,4-microstructure in the polybutadiene. These catalysts were developed by Bridgestone [246], [258], [259] and studied in other laboratories [260], [261]. The most common catalyst system consists of a nickel carboxylate with an alkylaluminum and BF_3 etherate or HF. These systems can give *cis*-1,4-contents of up to 98 % in the polymer, along with good reactivity at low levels of nickel and relative freedom from gel. As in most of the Ziegler – Natta catalyst systems used for production of polybutadienes, the molar mass of the resulting polymer is inversely proportional to catalyst concentration. Allenes, acetylenes, and vinylcyclohexane all retard polymerization and reduce molar mass. The molar mass decreases with increasing polymerization temperature. Most polymerizations described in the literature are carried out in either benzene or mixed aromatic – aliphatic solvents.

Neodymium-Catalyzed Polybutadiene. High-*cis*-polybutadiene can be prepared using some of the lanthanide elements as catalysts [262]. A basic patent was filed by Union Carbide in 1963 [263]. Considerable research work on the system has been carried out by Russian and Chinese scientists [264]. The preferred system seems to be based on neodymium. Commercial products are now made by Bayer and Enichem. Rare-earth systems are also in use in South Africa and China. The catalyst system consists of rare-earth carboxylates with alkylaluminum and a source of chloride, such as diethylaluminum chloride [265-267]. Bulky carboxylates are preferred to improve catalyst solubility. The reactivity is a function of the carboxylate chosen and of the chloride: neodymium ratio. The chain-transfer agents used in other Ziegler – Natta catalyst systems (olefins, hydrogen, allene, etc.) are inactive in this system [268]. In the neodymium system the molar mass is varied by using a hydride such as diethylaluminum hydride or diisobutylaluminum hydride.

The neodymium polybutadiene system gives rapid polymerization to achieve very high conversions. Monomer concentrations of 10 – 20 wt % are generally used. The upper concentration limit depends on the ability of the equipment to handle the highly viscous solution and on the efficiency of heat removal. The polymers obtained have a very broad molar mass distribution and thus a high solution viscosity.

The neodymium catalyst system does not tolerate aromatic solvents. Polymerization can be carried out in a variety of aliphatic and cycloaliphatic solvents, generally at 50 – 90 °C. The molar mass of the product is inversely proportional to the reaction temperature, and the *cis* content of the polymer declines slightly with increasing temperature. The system is not sensitive to water at part-per-million levels as are some other Ziegler – Natta systems.

High-*cis*-BR has been improved incrementally, but the basic product has not been altered significantly for many years. Most of the research has been concerned with process improvement to increase yield and reduce cost and environmental hazards. Research is directed toward solvent-free, so-called “gas phase” processes, whereby polymer particles fluidized in monomer vapors are formed. This technology is used for production of polyethylene and polyproplyene (⟶ Polyolefins – Gas-Phase Process, ⟶ Polyolefins – Gas-Phase Processes). Its application to production of high-*cis*-BR has been studied in a number of laboratories.

Syndiotactic 1,2-Polybutadiene. Syndiotactic 1,2-polybutadiene is produced only by Japan Synthetic Rubber in small amounts [269], [270]. This partly crystalline material is produced by using a Ziegler – Natta polymerization process. Although a 99.7 % 1,2-content can be achieved, the product is deliberately produced with only ca. 90 % 1,2-content to reduce the crystallinity to 15 – 30 %.

The polymer is produced with a cobalt catalyst and an alkylaluminum compound. Triphenylphosphine is added to give the syndiotactic 1,2-microstructure [271].

High-cis-Polyisoprene. Titanium catalysts are often used to make high-*cis*-polyisoprene [242]. Titanium tetrachloride together with trialkylaluminum was used in early work, and the catalysts currently in use appear to be very similar [244], [272-274]. This catalyst is not suitable for the production of high-*cis*-polybutadiene, but it can produce a *cis*-1,4-polyisoprene with a *cis* content as high as 97 % [275]. Isoprene is more easily polymerized than butadiene to form polymers with high *cis* content. Even lithium-catalyzed polymers have ca. 93 % *cis*-1,4-microstructure (see Section Lithium – Butadiene (Li-BR) and Lithium – Isoprene (Li-IR) Rubber).

The conditions under which the Ziegler – Natta catalyst components are brought together are quite important. In the preferred process, AlR_3 is slowly added to $TiCl_4$ in an aliphatic solvent at low temperature. Ethers and amines may be used to reduce gel and oligomer formation. The optimum molar ratio of titanium to aluminum is about one. This gives a good reaction rate and minimizes problems of oligomer formation. Molar mass can be influenced by controlling monomer concentration and temperature.

High-*cis*-polyisoprene and butadiene – isoprene copolymers can also be produced with *neodymium catalysts.* This may prove to be of interest because of its potential to produce improved polybutadiene products with low levels of the higher-cost isoprene monomer.

High-trans-1,4-Polyisoprene. Highly crystalline *trans*-1,4-polyisoprene can be produced by using various vanadium, titanium, or mixed vanadium – titanium catalysts [275], [276]. The VCl_3 system has been used commercially [277] because it produces less material with low molar mass and gives a higher overall *trans*-1,4-content. The process is usually performed at 20 – 90 °C. The addition of ethers or $Ti(OR)_4$ is claimed to increase the polymerization rate, which is otherwise slow [276], [278]. High solution viscosity necessitates operation at lower solids levels and this limits the productivity of the system. Aliphatic solvents are preferred because the solution viscosity is reduced in this case.

3.2.1.3. *Producers and Production Capacities*

High-cis-Polybutadiene. Production data on BR including high-*cis*-polybutadiene are given in Section Lithium – Butadiene (Li-BR) and Lithium – Isoprene (Li-IR) Rubber.

Of the high-*cis*-BR technologies, the *cobalt process* is most widely employed. B. F. Goodrich technology was licensed during the 1960s and 1970s in Canada, the United States, the Federal Republic of Germany, Japan, and Australia. Other plants were later built in Turkey, India, the People's Republic of China, and France. This technology has since been refined to produce *cis*-BR with low gel grades for productions of HIPS and to control branching. The more linear *titanium-catalyzed* polymers were first developed by Phillips. These are now produced in France, Germany, Japan, and the United States. *Nickel-catalyzed polymers* are produced in the United States, the People's Republic of China, and Japan. A more recently developed process is based on *neodymium*. High-*cis*-polybutadiene is now produced in the United Kingdom and Germany by this method.

Producers and trade names are listed in Table 19

Table 19. High -*cis*-polybutadiene producers

Company	Country	Trade name
American Synthetic Rubber Co.	United States	Cisdene
Australian Synthetic	Australia	Austrapol CB
Bayer	United States/ Canada/ Germany	Buna CB, Taktene

Bridgestone/ Firestone	United States	Duradene
Enichem	UK/ Italy	Europrene Neocis
Goodyear	United States	Budene
Japan Synthetic Rubber	Japan	JSR BR
Hyundai Petrochemical	Korea	
Indian Petrochemicals CL	India	Cisamer
Karbochem	South Africa	Neodene
Kumho Petrochemical	Korea	Kosyn
Michelin	France	
Nippon Zeon	Japan	NIPOL
Petkim	Turkey	Petcis
Petrochim	Romania	
Taiwan Synthetic Rubber	Taiwan	Taipol
Ube Industries	Japan	Ubepol
Voronezh SR	Russian Republic	SKD
Yefremor	Russian Republic	SKD

High-cis-Polyisoprene. Worldwide production of polyisoprene is presently difficult to estimate and subject to rapid changes. Most of the capacity is in Eastern European but the economics of these plants are marginal now and much of the capacity is shut down. The other major economic factor is the price of natural rubber which can fluctuate widely. Current producers and trade names are given in Table 20.

Table 20. High -*cis*-polyisoprene producers

Company	Country	Trade name
Goodyear	United States	Natsyn
Japan Synthetic Rubber	Japan	JSR
Nippon Zeon	Japan	NIPOL IR
Petkin	Turkey	Petcis
Petrochim	Romania	
Shell Nederland	Netherlands	(Li polymer)
Voronezh SR V/O Raznoimport	Russian Republic	SKI
Yefrenov V/O Raznoimport	Russian Republic	SKI
Shanghai GAO DIAO	People's Rep. China	

Syndiotactic 1,2-polybutadiene. is produced by Japan Synthetic (trade name JSR RB).

3.2.2. *Ethylene – Propene Elastomers (EPM, EPDM) [279-281]*

3.2.2.1. *Properties, Grades, and Applications*

Ethylene – propene elastomers are a family of random elastomeric copolymers with a completely saturated polymer backbone. These elastomers are therefore designated with an “M” according to the ASTM standard DIN/ISO 1629.

There are two basic types of ethylene – propene elastomers:

1. Ethylene – propene copolymers (EPM)
2. Ethylene – propene – diene terpolymers (EPDM)

The *copolymers* are generally amorphous elastomeric polymers without unsaturated bonds, thus necessitating the use of peroxide cure systems for vulcanization. The *terpolymers* contain small quantities (< 12 wt %) of a nonconjugated diene. Only one of the double bonds of each diene molecule takes part in polymerization, resulting in a saturated polymer backbone with a pendant double bond that facilitates the use of conventional sulfur curing.

Properties. The saturated carbon backbone structure accounts for the following features:

1. Outstanding ozone resistance
2. Excellent weathering stability
3. Excellent heat resistance (< 175 °C)
4. Good insulating properties
5. Low-temperature flexibility (glass transition temperature: ca. – 55 °C)
6. Good chemical resistance (toward polar organic and inorganic compounds)
7. Good moisture and steam resistance

EPM and EPDM have the lowest density (0.86 kg/L) of any commercial elastomer. In addition, during compounding, EP(D)M can be heavily loaded with oil and fillers resulting in low compound costs.

The structure of the polymer can generally be described by three features:

1. Ethylene: propene ratio and monomer sequence distribution
2. Molar mass and molar mass distribution
3. Content and type of diene incorporated

These structural features are directly related to the polymerization conditions. By varying the conditions, polymers with different properties can be obtained and a large selection can be provided, suitable for various applications.

As ethylene content increases:

Stress – strain properties improve
Green strength improves
Compression set deteriorates

Low temperature flexibility deteriorates
Hardness increases

As molar mass increases:

Stress – strain properties improve
Green strength improves
Extendability improves
Compression set improves

As diene content increases:

Stress – strain properties improve
Compression set improves
Cure rate increases
Heat aging resistance declines

The diene type (see Section Basic Chemistry and Production Processes) influences compound properties as follows: Ethylidenenorbornene (ENB) gives the fastest cure rate; dicyclopentadiene (DCPD) the best processability; and 1,4-hexadiene (HD) the best heat resistance.

The EP(D)M grades (ca. 250 available worldwide) are constantly optimized to fit specialty applications. Although many manufacturers produce particular grades which are reasonable substitutes for one another, EP(D)M elastomers are not standardized as are general-purpose rubbers. Listings of grades are summarized in [282].

Specifications. The amount of information provided by manufacturers in their specifications differs. Mooney viscosity — the basic qualitative index of molar mass and processability — is always specified. Mooney viscosity is usually expressed at 100 °C, 125 °C, or 150 °C. Higher temperatures are used for accurate Mooney measurements of higher molar mass grades with a Mooney viscosity > 80 – 100 at 100 °C. There are no absolute measurements of molar mass. Each manufacturer quotes his own set of numbers. The conditions under which the number is measured must be clearly specified in all cases. Oil content, if any, is given in phr. Some manufacturers specify ethylene content (40 – 80 wt %), diene content (0 – 12 wt %), iodine number, and maximum residues (e.g., 50 ppm transition metal, 0.3 % ash, 0.5 % water or volatiles content). Performance of a standard compound is usually given, including cure characteristics (delta torque, cure times), tensile strength (4 – 22 MPa). Elongation at break (150 – 800 %), and compression set (5 – 20 % after 22 h at 70 °C). Density varies according to diene content and crystallinity, but is in the range 0.86 – 0.90 kg/L.

Storage and Transportation. The rubber is generally shipped in boxes containing bales of 25 to 34 kg, multiunits of bales, or bags of pellets for certain semicrystalline grades. Rubber processors prefer loosely packed bales, whereas plastic blenders prefer pellets.

Uses. As a result of their versatility, EP(D)M polymers find use in a number of market segments, both in the traditional thermoset areas, and increasingly in thermoplastic blends and alloys. Typical applications for EP(D)M are given in Table 21.

Table 21. Applications of EPM and EPDM (1991)

Market segment	Market breakdown	Typical applications
Automotive	32 %	radiator/heater hoses, weatherstrips, window channels, sponge seals, mounts, car mats
Plastics modification	15 %	impact-modified polypropylene, thermoplastic olefins
Construction	14 %	roofing membrane, window seals
Industrial	11 %	steam and garden hoses, gaskets O-rings, mounts
Oil	10 %	oil viscosity improver
Electrical	6 %	cable jacketing, insulation, cable filler, connectors
Tire	4 %	sidewall construction, inner tubes, tire valves
Miscellaneous	8 %	footwear, carpet underlay

Uses in Tires. In the 1960s, EPDM was expected to become the new tire elastomer. But until recently, its utilization for tire applications has been limited to some inner tubes and to blends for white side-walls. The main deficiency of EPDM is inability to develop adhesion and to covulcanize with unsaturated polymers such as natural rubber, or polybutadiene.

The physical properties of blends with highly unsaturated rubbers are poor, due to a lack of co-cure between the polymers. The conventional explanation is that the unsaturated polymer is overcured before the EPDM phase in the blend can achieve a high state of cure. This is due to the very different cure rates of the two polymers. EPDM is generally much slower than highly unsaturated rubbers [283]. The physical properties of blends can be improved by modifying the EPDM with, for example, maleic anhydride [284], but this approach is too costly for tire applications.

In *blends with NR*, excellent physical properties and adhesion can be achieved when the EPDM has high molar mass and high (> 8 %) ethylidenenorbornene content [285], [286]. This concept is commercially being used in veneers for radial passenger tires. The veneer is resistant to weathering, since the EPDM phase is immune to ozone attack, and the NR phase domains are so small that cracks cannot easily grow. No chemical antidegradants are required in the formulation, so discoloration from staining antioxidants is avoided [287]. Development of this technology for tire sidewalls and other tire components is underway in tire companies worldwide.

3.2.2.2. *Basic Chemistry and Production Processes*

Monomers. The monomers ethylene and propene are normally used as polymerization grade (purity > 99 %) and must be free of impurities such as carbon monoxide, oxygen, water, acetylene, methanol, or methylacetylene (content < 10 ppm). These impurities are potent poisons of Ziegler – Natta catalysts, which are exclusively used for EP(D)M polymerization [281], [288].

Termonomers. The ideal termonomer has to meet several important criteria. It should have two double bonds of widely different reactivity. One double bond should react rapidly in the terpolymerization, while the second one should be relatively inert. However, this second double bond must be reactive toward the vulcanizing agent. The monomer should also be volatile, so that the residual unreacted monomer can be easily removed from the polymer after polymerization. Finally, the termonomer should be readily available and inexpensive. However, no termonomer meets all criteria. Many compounds have been investigated as possible termonomers [279]. Most research has been restricted to nonconjugated dienes as termonomers since they have minimal influence on copolymerization, yield normal molar mass distributions, and only introduce unsaturation in side chains. The different termonomers commercially used for EPDM are shown in Figure 13.

Figure 13. Termonomers used for production of EPDM

Ethylenenorbornene is the most commonly used termonomer because it reacts rapidly in the polymerization and gives high quality, fast curing elastomers. ENB polymers cure faster than polymers containing other termonomers. This is essential for high productivity in continuous curing extruded applications.

Dicyclopentadiene is used as a termonomer due to its low cost and its high reactivity in the polymerization. The main deficiency of DCPD terpolymers is their slow cure rate relative to terpolymers containing ENB. Another disadvantage is that DCPD can be easily cracked to cyclopentadiene (CPD) during stripping and monomer recovery operations. Catalyst efficiency is severely reduced, if CPD levels build-up in the process streams.

There are some similarities between DCP and ENB. Both molecules contain a seven-membered dicyclic norbornene ring in which one double bond is a member of a highly strained five-membered carbon ring. This double bond enters rapidly into the polymerization. The exocyclic ethylenic double bond in ENB is sterically hindered so it does not react during polymerization. In DCPD, the second double bond is not “protected” by steric hinderance. It can, therefore, take part in the polymerization leading to branching, cross-linking, and possibly gel formation. The processability of DCPD terpolymers is improved in comparison with ENB polymers because of the broadening of molar mass distribution as a result of branching.

1,4-Hexadiene (HD) is exclusively used by Du Pont. It is a linear nonconjugated diene. Polymerization favorably occurs via the 1,2 position because of the steric hindrance of the 4,5 double bond. In contrast to ENB and DCPD rings, HD is less reactive in polymerization due to the lack of bond strain. 1,4-Hexadiene has a low boiling point (66 °C) and is not separated from the solvent during the solvent recycle. The cure rate of EPDM using HD as the termonomer is slower than with EPDM using ENB and is comparable with DCPD as termonomer. Due to the relative absence of side reactions, compounds based on HD polymers show the best heat resistance of all EPDM vulcanizates. HD polymers are most suitable for post modification, e.g., reaction with maleic anhydride.

Catalysts. Commercial EP(D)M polymerization processes employ vanadium or titanium catalysts. Metallocene catalysts, although commercially used for polyolefin polymerization (⟶ Polyolefins – Coordination Catalysis) are currently in the pilot plant stage for EP(D)M polymerization [289-291].

Vanadium compounds are used more widely than titanium compounds as catalysts. Vanadium compounds are soluble in hydrocarbons and form an essentially homogeneous system, in addition the elastomeric polymers produced by these catalysts contain no or a minimal amount of crystalline, homopolymer fractions. However, vanadium catalysts are less active than titanium or metallocene catalysts (see Production Processes.).

The most widely used commercial vanadium compounds are vanadium oxytrichloride, vanadium tetrachloride, and vanadium trisacetylacetonate.

There are also many different aluminum alkyls which can be used as *cocatalysts* for EP(D)M polymerization. The most widely used commercial compounds are diethylaluminum chloride and ethylaluminum sesquichloride.

Reactivators. Catalyst efficiency (typically 800 – 8000 g polymer per gram vanadium) can be improved by using reactivators. The active oxidation state of vanadium is + 3; vanadium is reduced from oxidation state + 4 (VCl_4) or + 5 ($VOCl_3$) during alkylation [292]. Vanadium in the inactive oxidation state of + 2 can be reactivated by treatment with compounds containing active halogen atoms which can oxidize the deactivated vanadium species back to the + 3 valence state [293], [294]. Ethyl trichloroacetate and *n*-butyl perchlorocrotonate are commercially used. DSM has promoted the EP(D)M reactivator ethyl dichlorophenylacetate. It is claimed that this compound combines an excellent reactivation effect with lower residual vanadium and chlorine levels in the finished polymer [295], [296].

Molar Mass Control. In most Ziegler – Natta systems, the molar mass of the polymer is influenced by the type of solvent, the concentration of monomers, catalyst and reactivator, the temperature, the aluminum : vanadium ratio and the ethylene : propene ratio [288]. Trace levels of impurities can also have a significant effect on molar mass. As in homopolymerization, transfer agents such as hydrogen and diethyl zinc are widely used for the primary control of molar mass of the polymer during copolymerization.

Production Processes. At present, commercial EPM and EPDM polymers are produced by solution or suspension processes. Most manufacturers use a solution process. The reaction is homogeneous; the process is flexible and capable of producing many different grades of products. Enichem and Miles (Bayer) use a suspension process [281]. Both solution and suspension are continuous processes which typically consist of four operating sections, i.e., polymerization, momomer and solvent recycling, product recovery, and production finishing.

Solution Process. The schematic of a typical solution process is shown in Figure 14. Typcially, polymerization is carried out at 10 – 50 °C and 1 – 20 bar in a single continuous stirred-tank reactor (CSTR) (a). The polymerization is exothermic ($\Delta H \approx -2.4$ MJ per kilogram of polymer). The heat of reaction is removed by precooling the reactor feeds and/or evaporative cooling of the reaction mixture. The residence times in the reactor range from 15 – 60 min, depending on the catalyst employed, temperature, etc. Ethylene conversion is nearly complete in a single pass through the reactor. Unreacted propene is recovered and recycled to the polymerization. Solvent (usually hexane) and unreacted diene are also recovered for reuse after purification. Immediately downstream of the reactor, the polymerization is shortstopped with water, alcohol, or other polar liquids (b). The polymer solution is then mixed with water, aqueous sodium hydroxide, or dilute acid under vigorous agitation to remove catalyst residues (c). After addition of chemicals such as extender oils and stabilizers (d), the polymer solution is coagulated and stripped with steam and hot water to remove unreacted monomers and solvents (e). Antiagglomerants and antifoaming agents may be added to control crumb agglomeration and facilitate the separation of gas and liquid. The rubber crumb is then passed over a screen (f) to remove free water and subsequently dried. Either extrusion drying or hot air drying may be used. EP(D)M is sold in the form of crumb, bales, or pellets.

Figure 14. Solution process for production of EPM/EPDM [297], [298]

a) Reactor; b) Shortstopping section; c) Separation of catalyst; d) Addition of chemicals; e) Steam stripping section; f) Screen; g) Expeller; h) Expander

Suspension Process. Suspension polymerization is carried out in an excess of liquid propene. The polymer precipitates out of the reaction medium as soon as it is formed. Consequently, the viscosity increase in the polymerization medium is negligible, compared with that of solution polymerization. The solids content in the reaction medium can therefore be higher than in the solution process, e.g., 20 – 30 wt % instead of 5 – 10 wt %. Monomer recovery, stripping, and finishing are carried out as described for the solution process except that the coagulation step is not required since the polymer already exists as particles. The slurry process is well suited to the production of grades with high Mooney viscosity, which can be oil extended for easier processing.

Dutral (now Enichem) is running a *simplified suspension process* for the production of EPM, using a highly active catalyst based on titanium. The product is recovered directly from the suspension in an extruder-based system, without the prior catalyst residue removal. The unreacted monomers are recycled to the reactor without treatment or distillation [299], [300]. This new slurry process offers the advantages of reduced capital and operating costs. However, presently this process is limited to the production of EPM. Unfortunately, polymers produced with titanium catalysts tend to have a less random monomer

sequence distribution compared with existing vanadium-based commercial copolymers [281], due to multiple active sites with titanium compared with essentially single sites with vanadium.

Gas-Phase Polymerization. Gas-phase polymerization is now commonplace for polyolefins [301], [302] (⟶ Polyolefins – Gas-Phase Process) and some types of modified polypropylenes (reactor-modified thermoplastic olefins) (see Section Thermoplastic Polyolefins) [303]. Extension of this technology to the full range of elastomeric co- and terpolymers is in the advanced pilot plant stage [304-306]. A schematic of the overall Union Carbide gas-phase process is shown in Figure 15.

Figure 15. Gas phase EPM/EPDM process of Union Carbide [307]

a) Monomer purification; b) Cycle cooler; c) Cycle compressor; d) Fluidized-bed reactor; e) Product discharge; f) Monomer separation; g) Balers/baggers

Monomers and catalysts are fed to the reactor (c) and the product is removed intermittently. Heat of reaction is removed by circulating the fluidizing gas through heat exchangers outside the reactor. The process uses no solvents and does not require a catalyst residue removal step. Solvent stripping and recovery operations are avoided, although unreacted monomers must be purged before discharging the product. In principle this technology offers the advantages of reduced capital and operating costs when compared to the conventional processes. It has yet to be proven, however, that the fluidized-bed process can produce as wide a range of products, having the same or comparable properties (e.g., high ENB or low Mooney) as those produced by existing processes and that the product grade changeover time is not prohibitive.

3.2.2.3. *Producers and Production Capacities*

The commercial production of EPM and EPDM started in the early 1960s. Today EP(D)M has the largest market volume of all special elastomers: 601 000 t in 1992 [308]. With a growth rate of ca. 4 % per year, the EP(D)M consumption is predicted to increase to 726 000 t by 1996. In 1992, the production capacity of the 12 EP(D)M manufacturers that operate 15 plants was ca. 854 000 t. Table 22 gives an overview of the EPM/EPDM producers, their plant locations, their production capacities (1992), and their trade names.

Table 22. EPM/EPDM producers, locations, production capacities (1992), and trade names [308]

3.3. Synthesis of Butyl Rubber by Cationic Polymerization [309], [310]

Butyl rubber is a copolymer of isobutene (2-methylpropene) and a small amount of isoprene (2-methylbuta-1,3-diene, 1 – 3 mol %). It is abbreviated IIR in the ISO nomenclature (ISO 1629, 1987) (butyl rubber see Section Nomenclature and Classification). The isoprene units introduce unsaturated sites into the polymer chain to enable vulcanization. Historically, butyl rubber was the first saturated polymer into which limited olefinic functionality was deliberately introduced [311]; EPDM (see Section Ethylene – Propene Elastomers (EPM, EPDM)) is a more recent example of the same principle.

The principal structure of the polymer chain is as follows:

$n >> m$

3.3.1. *Properties, Grades, and Applications*

3.3.1.1. *Properties*

The most significant property of butyl rubber that differentiates it from the other hydrocarbon elastomers, is low permeability to gases; most significantly, in practice, to air and water vapor. Due to its low resilience, butyl rubber is also used when vibration damping is important. For applications, butyl rubber is compounded with fillers, plasticizers, and curing agents (see Section Applications)

The highly saturated IIR chain is resistant to chemical attack. Thus IIR compounds exhibit better heat and ozone resistance than highly unsaturated elastomers such as BR, NR, and SBR. IIR also has excellent resistance to acids, bases, and other chemicals. As are all hydrocarbon polymers, IIR is highly swollen by gasoline and other hydrocarbons. Butyl rubber has good electrical insulating properties and is biocompatible [312]. As a viscoeleastic material, uncured IIR creeps (cold flows) at ambient temperature. This deformation is prevented by vulcanization (i.e., cross-linking via the isoprene units).

Typical properties of the *uncured polymer* are as follows [313]:

Density	917 kg/m^3
Glass transition temperature	– 70 °C
Heat capacity	1.95 kJ kg^{-1} K^{-1}
Thermal conductivity	0.130 W m^{-1} K^{-1}
Refractive index	1.51
Dielectric constant (at 1 kHz)	2.38
Dissipation factor (at 1 kHz)	0.003

The proton NMR spectrum of IIR has singlets at 1.1 and 2.3 ppm from tetramethylsilane (TMS) due to the methyl and methylene groups of the polyisobutene, a triplet at 5.1 ppm that stems from the single hydrogen attached to the double bond [314], as well as a peak around 4.9 ppm that has been identified as a branching point [315]. The isoprene content listed in Table 23 is the sum of the regular and the branched structures.

3.3.1.2. *Grades*

Each producer listed in Table 24 makes several grades of IIR, which differ primarily in the amount of isoprene and the Mooney viscosity (i.e., molar mass and molar mass distribution). Equivalent grades of the two main producers are listed in Table 23 together with illustrative values of specified or important properties. The actual specification ranges differ slightly for different producers, the comparison in Table 23 being based on Mooney Viscosity.

Table 23. Selected grades and properties of IIR

Producer	Butyl grade			
Bayer	100	101–3	301	402
Exxon	065	007	268	365
Mooney viscosity[a], MU	33±3	51±5	51±5	33±4
Isoprene content[b], mol %	0.9±0.2	1.75±0.2	1.85±0.2	2.25±0.2
Cure characteristics [c]				
Maximum torque, dN · m	64±6.0	–	82±6.0	87±6.0
Minimum torque, dN · m	11±4.5	–	16.0±4.5	11.5±4.5
Antioxidant content[b], min wt %	0.03 min	none	0.03	0.03
Ash content[d], wt %	0.3	0.3	0.3	0.3
Volatiles content, max %	0.3	1.0	0.3	0.3

[a] Bayer grade according to ASTM D 1646, ML/1+8 (125 °C).
[b] Bayer standard method.
[c] ExxonMobil grade according to ASTM D-2084, modified (rheometer ODR 2000).
[d] According to ASTM D 5667.

3.3.1.3. *Specialty Rubbers*

Specialty rubbers include Bayer's XL 10000, a cross-linked grade containing DVB [313], and Exxon's Star-branched butyl rubber, containing 5–20 % of a very high molar mass branched fraction [316, 317]. The latter was introduced by Exxon Chemical Co. in 1989. A broad, bimodal molar mass distribution was achieved using branching agents in the polymerization. One mode consists of normal linear chains, as previously described. The second mode consists of branches of normal chains connected through an SBS polymeric branching agent added to the polymerization. The concept was labeled “Star-branched butyls”, and exhibits higher green strength and faster stress relaxation.

3.3.1.4. *Applications*

The majority of the IIR produced is used captively by manufacturers as base polymer for halobutyl rubber production, discussed in Section Halobutyl Rubber. A significant portion of the remainder is used in tire-related applications: inner tubes, tire-curing bladders, or as blends with BIIR—inner liners. A small amount of this is used in other applications, principally sealant tapes and caulks, pharmaceutical closures, membranes for roofing and water retention, and various mechanical seals and mounts.

For most applications, IIR is vulcanized via the isoprene units to cross-link the individual polymer chains into a network. Vulcanization or curing is carried out commercially by three methods, using sulfur, phenolic resins, or quinone dioximes as curing agent. Of these methods, accelerated sulfur cures are used for most applications, phenolic resin cures are used for making tire-curing bladders, and quinone dioxime cures are used infrequently.

The measured properties of the vulcanizate are affected by the method and extent of cross-linking and by the quantity and type of fillers and plasticizers used.

IIR is also used as a component of food and in the manufacture and storage of foods. IIR is an allowed component of chewing gum in most countries [318]. Bayer's XL 10000 may be used in sealing cements, and is also commonly used in condenser caps [315].

3.3.2. *Basic Chemistry and Production Processes*

3.3.2.1. *Basic Chemistry*

Butyl rubber is composed of linear polyisobutene chains with isoprene units distributed randomly along them [319]. The isobutene moieties are linked exclusively head to tail; the isoprene units have mainly the *trans*-1,4-configuration, with about 10 % of the branched structure [315].

The copolymerization of isobutene and various monomers such as isoprene or isoprene and DVB (divinylbenzene) is a carbocationic process. This is initiated by a species resulting from an activated Lewis acid such as AlX_nR_{3-n} (X = Cl, n = 1 – 3, R = Et) in the slurry or solution process [320], [321]. The Lewis acid is activated by protogenic compounds such as water, hydrochloric acid, or hydrogen sulfide. Specialty rubbers such as XL10000 (Bayer) or Star-branched butyl (ExxonMobil Chemical) can be formed by the addition of a third monomer during the polymerization (see Section Specialty Rubbers). The mechanism of the copolymerization is still not fully understood; the generally accepted scheme is given below:

Initiator formation (speculated)

Initiation

Propagation

Chain transfer

Termination

Alternative mechanisms have been proposed [322].

The incorporation of isoprene is governed by the ratios of homo- and cross propagation rate constants, $r_{1B} = k_{11}/k_{12}$ and $r_{1P} = k_{22}/k_{21}$, where isobutene and isoprene are referred to as monomer 1 and 2, respectively. It was shown that the composition of butyl rubber can be described by r_{1B} alone [315]. The rate constant for isobutene homopolymerization is $k_{11} = (6 \pm 2 \times 10^8)$ L mol^{-1} s^{-1} but this number has always been a source of heated debate [323].

Industrially the copolymerization is carried out at low temperature (ca. – 90 °C) in order to obtain high molar masses. The strong dependence of molar mass on temperature is due to the high activation energy of chain transfer relative to that of the polymerization. In the production process of butyl rubber, isoprene is both the dominating poison and chain transfer agent. In general, most unsaturated and substituted hydrocarbons and some alkyl halides affect the polymerization.- The compounds classified as “poisons” reduce the degree of conversion, while those classified as “chain transfer agents” reduce the molar mass (Mooney viscosity) [324]. The *slurry process* uses chloromethane as a diluent, while the *solution process* uses a hydrocarbon such as isopentane as solvent. Both solvents are inert in terms of polymerization chemistry. Although isobutene is believed to polymerize by a carbocationic mechanism only [312], alternative mechanisms such as a radical – cationic [325] or a cationic – coordination [326] mechanism have been suggested. The claim of the cationic-coordination mechanism has yet to be substantiated but continues to be an area of considerable research due to the cost saving that could be realized by not having to polymerize at ca. –90 °C. Considerable research effort is being directed towards a system that would allow copolymerization at higher temperature [327].

3.3.2.2. *Industrial Production*

Historical Development. During the late 1920s M. OTTO working at the IG Farben laboratories in Germany, investigated synthetic oils made by polymerizing olefins with strong acids. He made the important discovery that the polymerization temperature regulated molar mass. By chilling isobutene with dry ice before addition of boron trifluoride catalyst, OTTO succeeded in making rubberlike products instead of oils. Around 1930 F. A. HOWARD, the President of Standard Oil Development Company, visited Germany and learnt of OTTO's discovery. In 1932 OTTO, invited by HOWARD, came to the USA and worked with R. M. THOMAS to exploit the polymers of isobutene. The process for manufacturing butyl rubber was further developed by R. M. THOMAS and O. C. SLOTTERBECK at Standard Oil Development Company (Esso, now Exxon) (Linden, New Jersey, United States). They firstly used butadiene and then isoprene to introduce sites for vulcanization. During World War II, most of the world was cut off from natural rubber supplies in the Far East and, in a remarkably brief time, large-scale manufacturing of various synthetic rubbers was implemented in North America [328, 329].

The first commercial-scale production unit came into operation in 1943 in Baton Rouge, Louisiana. Units in Baytown, Texas, and Sarnia, Ontario, Canada, followed in 1944.

Today, butyl rubber is produced by two different processes, the slurry and the solution processes. The vast majority of butyl rubber is produced by the slurry process, so this will be discussed in more detail.

Raw Materials. The monomers used for both production processes of butyl rubber, isobutene, and isoprene are extracted from internal petroleum refinery streams (⟶ Butenes – Upgrading of Butenes; ⟶ Isoprene – Recovery from C_5 Cracking Fractions (more details in [330])

Slurry Polymerization Process. In the traditional method of manufacture, practiced since 1943, an aluminum trichloride catalyst is used with a small quantity of water as cocatalyst in chloromethane as diluent. The terms catalyst and cocatalyst reflect established industrial usage; the correct terms are initiator and coinitiator, respectively [312]. The catalyst solution (0.2 wt % $AlCl_3$ in chloromethane with a small amount of water) is prepared by passing pure and dry chloromethane through a bed of solid $AlCl_3$ (Fig. 16, a). Water is added to this concentrated solution, which is further diluted with chloromethane

and chilled to the reaction temperature. The catalyst is quite active; the polymer to catalyst mass ratio is normally on the order of several thousands. The catalyst activity is proportional to the water content of the catalyst solution in the low concentration range. Excessive amount of water destroys the catalyst. The catalyst solution is then fed into the reactor together with the monomer feed. The nominal isobutene cocentration in the feed is ca. 30 wt %. The reaction is carried out continuously in an intensely agitated vessel (Fig. 16, b) at ca. – 90 °C. The polymer is formed instantaneously, and since it is insoluble in the diluent, precipitates as a fine slurry (particle size 10 – 30 µm). Agglomeration is not a problem because the rubber is below its glass transition temperature of – 70 °C. The slurry circulates through concentric rows of heat-exchanger tubes surrounding a central draft tube. The circulation : feed ratio is very high (> 100), but kinetic analysis showed that the reactor flow regime is closer to that of a plug flow reactor than that of a continuous stirred tank reactor because of the extremely high reaction rate [331]. The heat of reaction (– 0.8 MJ/kg) is removed by boiling subatmospheric ethylene in the reactor jacket.

a) Dissolver; b) Catalyst tower; c) Recycle tower; d) Recycle gas dryer; e) Reactor; f) Flash drum; g) Vacuum stripper; h) Finishing extruders

Reactor Control. Reactors are controlled to produce the desired molar mass of polymer, measured as Mooney viscosity, with the catalyst flow as the principal control variable. An increase in catalyst flow decreases the Mooney viscosity. The isoprene content of the polymer, the second most important control parameter, is determined by the composition of the feed together with the degree of conversion. The reactors are run typically at incomplete conversion for better control. Due to the poisoning effect of isoprene, conversion decreases with increasing isoprene content in the feed. The catalyst flow also has an effect on conversion; thus controlling this process is not easy. The reactors are operated intermittently because of fouling of the heat exchanger surfaces. When the control of the reactor cannot be maintained due to temperature increase, the operations are stopped and the reactors washed. To reduce or prevent fouling, the use of slurry stabilizing agents [332] or addition of 3 – 13 % solvent such as hexane to the feed has been patented [333].

Product Recovery and Finishing. The reactor discharge stream is treated with steam and hot water in a flash drum (Fig. 16, f). Most of the chloromethane and the unreacted monomers are flashed off and the water is separated from the vapors by condensation and subsequent adsorption on activated alumina (d). This step sometimes is proceeded by absorption in glycol. The dried stream is separated by distillation (b, c) into a chloromethane – isobutene stream for feed make-up, a pure chloromethane stream for catalyst make-up, and streams which must be purged from the recycle loop to prevent build-up of unwanted impurities. The polymer is recovered in the form of a wet crumb (6 – 10 wt % rubber in water). To control agglomeration, salts of fatty acids are added in the flash drum. Antioxidants are also added at this stage and sodium hydroxide is added to neutralize catalyst residues. The rubber is converted into the final commercial bale form by further drying. Most of the water is separated by draining, followed by drying extruders and finished by a final drying step in a fluidized bed. The dry rubber is cooled, baled, and packed into boxes or crates for shipment.

When the polymer from the reactor is to be processed further, such as by halogenation (see Section Halobutyl Rubber), the product may be recovered directly as a solution by discharging the reactor content into a hot solvent such as hexane. A further stripping stage is followed by adjusting the rubber concentration to the desired level for further processing, typically 20 – 25 wt % [334]. It is important to remove unsaturated residues before halogenation, otherwise these unsaturated substances would be halogenated, producing undesirable compounds.

Solution Polymerization Process. A process developed in the Soviet Union operates at – 60 to – 90 °C using a hydrocarbon solvent, such as isopentane and an aluminum alkyl halide catalyst [321]. This eliminates chloromethane and makes the water slurry step superfluous when the polymer is to be treated further in solution. However, the polymer concentration in the solution is necessarily lower than that possible in a slurry because the effect of concentration on effective viscosity is greater in solution, which reduces heat-transfer efficiency. Despite the decreased demand for refrigeration, the presence of the additional diluent leads to energy costs higher than those for the slurry process.

3.3.3. *Producers and Production Capacities*

Worldwide, several companies produce butyl elastomers in many different countries. However, the most prominent producers are Bayer AG and ExxonMobil Chemical with collectively two-thirds of the world production capacity. Worldwide production facilities for butyl and halobutyl rubber are listed in Table 24 [335], [336]. The capacities given refer to polymerization, with the exception of Japan Butyl's Kashima plant, which is a halogenation facility only. In general, many of the production facilities are multifunctional, able to produce butyl or halobutyl rubber on demand. The global nameplate capacity was 972 × 10^3 t in 2001.

Table 24. Producers and production capabilities of butyl and halobutyl rubber

	Producer	Location	Plant	Nameplate, 10^3 t/a
North America	Bayer Inc.	Sarnia, Canada	Butyl I + II	140
	Exxon Mobil Chemical	Baytown, USA		121
	Exxon Mobil Chemical	Baton Rouge, USA		132
Western Europe	Bayer	Antwerp, (B)	B.R.N.V.	115
	Exxon Chemical	N. Dame de Gravenchon (F)	Socabu	56
	Exxon Chemical	Fawley (UK)		93

	Sintezkauchuk	Togliatti, Russia		35
	Pitesti	Romania		5
Asia	Japan Butyl	Kawasaki		80
	Company	Kashima		35
	Yan Shan Petrochemical	Yan Shan (Beijing), China		30
	Reliance Industries	Hazira, China		25
World total				972

Since the 1970s the relative amount of IIR used has been decreasing and the amount of halobutyl rubber increasing. Differences in the relative amounts of IIR and halobutyl rubber used in different regions reflect the relative number of tubed and tubeless tires.

3.3.4. *Storage and Transportation*

IIR is packaged in 34 kg bales wrapped in synthetic polymer films, and shipped in crates or skids depending on customer needs.

IIR is considered a nonhazardous material for shipping and storage [337]. Stabilized grades should be used within five years of their date of manufacture, after which the molar mass may decrease significantly. The molar mass of grades without antioxidant can decrease after six months of storage.

3.3.5. *Legal Aspects*

The allowable uses and restraints of IIR in foods and storage of foods are covered by regulation of individual countries. These usually follow the United States FDA CFR, although local differences may occur.

The grades of IIR used in chewing gums, Bayer Butyl 101–3 and Exxon Butyl 007, contain no added antioxidant and are made with food-grade fatty acid. The use of IIR in *food manufacture* and *storage* is usually restricted to nonfat or low-fat foods [168]. In these applications, constraints are placed on the types and levels of antioxidants used. If the IIR is vulcanized, the curatives and other additives in the compound are also subject to restrictions.

3.3.6. *Toxicology and Occupational Health*

IIR is a nonhazardous material, and no special precautions are required in its handling [169]. It is generally used in cured compounds, and precautions for handling curatives and other compounding ingredients are frequently more significant.

Butyl rubbers contain only small amounts of the residual monomers isobutene and isoprene, typically < 100 mg/kg in each case. To date, no threshold limit value has been established for either monomer, since they both exhibit very low *acute toxicity*. The 2 h LC_{50} in mice is 415 g/m^3 and 157 g/m^3 for isobutene and isoprene, respectively [338].

A modified Ames test of isobutene showed that it is not mutagenic. Only traces of chloromethane (< 1 mg/kg) are found in butyl rubbers. Thus, the maximum airborne concentration released during processing should be well below the 50 mL/m^3 (8 h weighted average) occupational exposure limit set by the ACGIH.

Butyl rubber will not burn unless its surface temperature reaches 300 – 500 °C and an ignition source is available. Burning butyl rubber gives off dense black smoke and toxic gases such as carbon monoxide and hydrocarbons, resulting from incomplete combustion.

4. Synthesis by Radical and Other Mechanisms

John Dunn, Hermann Meisenheimer, Roland Steiger, André Marbach, Klaus M. Diedrich

4.1. EVM and Ethylene Copolymers

4.1.1. *Properties, Grades, and Applications*

Two copolymers of ethylene are industrially important in the solid rubber sector: ethylene – vinyl acetate copolymers, EVM [24937-78-8], and ethylene – methyl acrylate copolymers, AEM [25103-74-6].

EVM grades containing *between 40 and 80 wt % vinyl acetate* have elastomer properties. Their glass transition temperatures T_g are between –36 and 0 °C [219, 235, 236]. Their Mooney viscosities ML 1 + 4 (100 °C) are between 15 and 35 Mooney units, depending on the production process; thus EVM belongs to the readily processible rubbers.

Ethylene – vinyl acetate copolymers with *vinyl acetate content < 40 wt %* have pronounced partial crystallinity and can be processed thermoplastically. Copolymers with > *80 wt % vinyl acetate* are amorphous and have a T_g greater than 0 °C.

Ethylene – methyl acrylate solid rubber grades with methyl acrylate contents between 55 and 70 wt %, and Mooney viscosities ML 1 + 4 (100 °C) between 15 and 30 Mooney units, are available commercially. Their glass transition temperatures lie between –36 and –20 °C [237].

All other ethylene copolymers produced in industry are thermoplastics and are therefore not dealt with here [341], [342].

The following properties can be achieved by proper compounding in vulcanizates based on EVM or AEM:

1. Heat resistance up to 175 °C
2. Halogen-free
3. Good weathering, ozone, and UV resistance
4. Swelling in mineral oil of 0 – 100 vol % (depending on vinyl acetate or methyl acrylate content)
5. Satisfactory low-temperature properties (T_g between – 36 and 0 °C, depending on vinyl acetate or methyl acrylate content)
6. Satisfactory mechanical properties

The basic properties of EVM and AEM vulcanized rubbers are closely related to their chemical structures. The saturated methylene main chain and the associated thermal stability are common to both (see Fig. 17 and Table 4). EVM is only exceeded by silicone and fluorine rubber in its thermal stability [343]. Noticeable decomposition with loss of acetic acid occurs only above 170 – 180 °C [219]. The high resistance to weathering, ozone, and UV irradiation, of both EVM and AEM are attributed to the saturated polymer main chain.

Figure 17. Structure and basic properties of ethylene – vinyl acetate rubber (EVM) [235]

A) Heat, ozone, weather, and UV resistance; B) Low oil swell; C) Compatibility to nonpolar compounds; D) Preferred cure sites for peroxide curing

Both rubbers are halogen free, which is important with regard to their fire protection behavior (formation of halogen-free combustion gases).

The properties of EVM and AEM depend highly on the comonomer content. For a partially crystalline, branched polyethylene, the ethylene sequences capable of crystallization are distorted by the incorporation of vinyl acetate or methyl acrylate. Thus, with increasing co-monomer content the proportion of noncrystalline material also increases [219], [342], [344]. An EVM with 60 wt % vinyl acetate is completely amorphous.

With increasing crystallinity (increasing ethylene content), the polymers become harder, more rigid, and less permeable to gas or steam. The transparency also decreases [219], [342], [345]. The resistance of EVM and AEM toward nonpolar oils and fuels increases with increasing content of polar vinyl acetate or methyl acrylate groups. In contrast, the mobility of the polymer chains and the low-temperature flexibility decrease [236], [346], [347].

In accordance with the Gordon – Taylor relationship [348] the *glass transition temperatures* of the copolymers should vary linearly between the T_g of a purely amorphous low-density polyethylene (– 120 °C) [349] and that of a poly(methyl acrylate) (+ 6 °C) [350] or poly(vinyl acetate) (+ 29 °C/ +42 °C) [350]. For the Tg of poly(vinyl acetate) various data have been reported such as 35 °C [351] or 42 °C [352]. The Tg is dependent on molar mass [353]. Samples prepared in experiments in solution have a Tg between 39 and 42 °C. However, copolymers with low vinyl acetate content have a higher T_g than expected.

For partially crystalline ethylene – vinyl acetate copolymers (< 55 wt % vinyl acetate), T_g values are between –38 and – 30 °C and depend only slightly on the vinyl acetate content (see Fig. 18). Commercially available AEM grades have a T_g of –31 °C (55 wt % methyl acrylate) and – 20 °C (69 wt % methyl acrylate).

Figure 18. Glass transition temperature T_g and enthalpy of fusion ΔH of ethylene – vinyl acetate copolymers (DSC, second heating, 20 K/min)

Electrical properties also vary with the proportion of polar groups. The specific volume resistance ϱ_D of EVM decreases with increasing vinyl acetate content. From 0 to 150 °C, ϱ_D values are between 10^{17} and 10^{10} Ω · cm.

EVM and AEM rubbers are radically cross-linked, preferably with organic peroxides [343], [354-357]. To increase the rate and degree of cross-linking of EVM, low molar mass, polyfunctional vinyl compounds, such as triallyl cyanurate or triallyl phosphate, are added as well as peroxide [358], [359]. Cross-linking by using high-energy radiation (β radiation) is also possible [360].

Some commercial AEM grades contain ca. 4 wt % of a vinyl carboxylic acid (such as acrylic acid, maleic acid, or monoethyl maleate) as so-called cure site molecules [346], [361], [362]. These terpolymers are cross-linked with hexamethylenediamine and diphenylguanidine. Such nonradical cross-linking can improve the mechanical properties of the vulcanizate. Nonradical cross-linking of EVM by using alkyl aluminum compounds has been reported [363].

Applications.
Ethylene – Vinyl Acetate Rubbers. The main areas of application of EVM rubbers are in the cable sector, adhesives, and the modification of thermoplastics. As a result of the increasing high-temperature requirements in the automotive industry, EVM is being introduced for use in hoses and seals. EVM also has excellent dynamic properties which make it a suitable material for roll covers.

In the cable sector, EVM is used in heat-resistant electrical insulation (e.g., in floor heating, ignition wires, night storage heaters, rear window heating, electric motors, toasters, grills); in halogen-free cable sheathing; and in easy-peel conductive layers over medium-voltage insulation (underground cables) [345].

The so-called flame-retardant, noncorrosive (FRNC) application is especially important. EVM vulcanizates containing flame-retardant fillers, such as aluminum hydroxide, magnesium carbonate, magnesium hydroxide, or zinc borate, meet the most stringent safety requirements in case of fire [364]. They are characterized by

1. Low flammability
2. Low combustion gas density
3. Corrosion-free combustion gases

Wires and cables, as well as floors and noise absorption mats based on EVM, offer increased safety for people and materials in the event of fire. They are used, for example, in subways, shops, offices, hospitals, ships, control stations, computer centers, and radio or television stations. Underground conveyor belts based on EVM also satisfy strict flame resistance regulations [365], [366].

Ethylene – vinyl acetate has a low polymer viscosity for a solid rubber. Therefore, in the preparation of conductive compounds for medium-voltage cables, electrically conductive carbon blacks can be easily dispersed without the addition of plasticizers. The latter would considerably impair the dielectric properties of the insulation.

Another important reason for the use of EVM as a conductive layer in cable construction is the ready removal of this layer during mounting in the cable duct (banana peel effect) [345].

EVM copolymers with up to 45 wt % vinyl acetate are used as solvent-free, hot-melt adhesives [367], [368]. Formulation with waxes permits control of the melt index and the viscosity of the molten adhesive. Adhesion is strengthened by the addition of adhesive resins. EVM copolymers with 50–80 wt % vinyl acetate can also be used as pressure-sensitive adhesives (PSA) [369].

In contrast to most common thermoplastic ethylene-vinyl acetate copolymers with low vinyl acetate content, EVM copolymers can be processed easily for thin-layer applications. The specific molar mass distribution allows the preparation of high quality, transparent and homogeneous composites, either as cast film or as blown film [369], [370].

EVM copolymers are also suitable for *modifying thermoplastics*, such as poly(vinyl chloride) (PVC) [371], [372], styrene – acrylonitrile copolymers (SAN) [373], and cellulose esters [374]. For example, EVM – PVC graft polymers with 5 – 10 % EVM (45 wt % vinyl acetate) give impact-resistant products, which are used in plastic windows [372], [375]. EVM copolymers with 60 – 70 wt % vinyl acetate are completely compatible with PVC and function as polymeric plasticizers. These types of mixtures are processed to give sheets for car fittings.

Low molar mass EVM copolymers with up to 40 wt % vinyl acetate are also used as flow improvers for crude oil and middle distillates [376].

Ethylene – vinyl acetate copolymers can be completely or partially saponified. Here the ester groups are formally converted into vinyl alcohol units, with loss of acetic acid. EVM grades modified in this way are suitable for woven tissue coatings [377] and as hot-melt adhesives [378]. Other applications are in pigment dye printing, paints for paper, and varnishes [379], where they are used as thickeners.

Ethylene – Methyl Acrylate Rubbers. The primary uses of AEM rubbers are in car construction [346], [380]. Because of their good oil-resistance – low-temperature flexibility relationship (see Table 4), they are used for seals, bellows, hosing, and O-rings [346], [361], [362], in addition to cable and wiring insulation [381], [382].

4.1.2. *Basic Chemistry and Production Processes*

Polymerization Mechanisms. The radical copolymerization of ethylene and vinyl acetate has been known since 1938 [383]. At 1000 bar and 90 °C the copolymerization parameters r_1 and r_2 are nearly 1 for both monomers (see also ⟶ Plastics, General Survey – Copolymerizations) [384-386]. Higher r values have been found for ethylene at elevated temperature [387]. Higher rates of ethylene incorporation with increasing pressure have also been found [388]; this was attributed to heterogeneous reaction conditions (phase separation) [389], [390].

NMR investigations confirm the random distribution of monomers in EVM-type copolymers [391], [392].

Polymerization is initiated with peroxides, peresters, hydroperoxides, or azo compounds [341]. The choice of initiators depends on the polymerization temperature and the desired polymerization time. Important crude polymer properties, such as short-chain branching, depend strongly on these parameters [393].

An ethylene – vinyl acetate copolymerization has been described on a laboratory scale that uses organometallic catalysts. The catalysts are based on

rhodium(III) chloride – triethylaluminum complexes [394].

Production of EVM Rubber. EVM solid rubber is produced in industry by three processes (see Fig. 19).

Figure 19. Production processes for ethylene – vinyl acetate copolymers

High-Pressure Process. The high-pressure or bulk process [219] is similar to the production process for low-density polyethylene (LDPE) (⟶ Polyolefins). It is carried out at 1000 – 3000 bar and 150 – 350 °C without the addition of solvents. Stabilized vinyl acetate is first mixed with precooled ethylene, which has been compressed to 100 – 500 bar. The monomer stream is compressed further and charged continuously to a stirred autoclave or tube reactor [341]. The initiator solution and, if required, a chain-transfer agent (e.g., an alkane, ketone, or aldehyde) are injected. The conversion is 10 – 20 %, based on the monomers. The reaction mixture is then depressurized in stages; the residual monomers are separated and recycled to the reaction. The polymer melt is chilled and pelletized. Monomeric vinyl acetate has chain-transfer properties that limit the molar mass of the polymer chain [343]. As a result of the high monomer concentration in the high pressure process, only relatively low average molar masses can be obtained with copolymers with high vinyl acetate content [219]. High-pressure EVM products are therefore produced only up to a vinyl acetate content of 45 wt % and Mooney viscosities of 15 – 20 Mooney units.

Solution Process. The solution process [395-397] is operated in the medium-pressure region (200 – 1000 bar) at 50 – 120 °C by using solvents with low transfer constants. Suitable solvents are *tert*-butanol [395-404], benzene, toluene, methyl acetate [219], methanol [405-407], and dialkyl sulfoxides [408]. The process enables the production of gel-free copolymers [400], [401] that are characterized by high Mooney viscosity (20 – 35 Mooney units) at high vinyl acetate content (40 – 80 wt %).

Polymerization occurs in a cascade of stirred-tank reactors at conversions of 50 to 70 %. During workup the product solution is freed from solvent and residual monomer. Pellets 2 – 4 mm in size are finally produced for formulation, which give a free-flowing material when treated with a suitable coating to lower the self-adhesion of polymer particles.

Emulsion Process. The emulsion process [409] operates between 30 and 70 °C at 1 – 200 bar. The polymers have vinyl acetate contents between 60 and 100 wt % and are produced as latices. The products are not suitable for vulcanization because of their high proportion of gel. Dispersions of EVM copolymers are used as binders for exterior paints and plasters, as components of wood adhesives, and as thickeners in varnishes [379].

Production of AEM Rubber. AEM solid rubbers were first introduced in 1975 as filler-containing masterbatches by Du Pont [346]. No production processes are described in the literature. However, AEM is often produced alternately with EVM in the same high-pressure plants. Although acrylates are clearly more reactive in polymerization than ethylene [342], the process gives random ethylene – methyl acrylate co- and terpolymers [346]. Therefore, either low conversions are used or methyl acrylate is added stepwise [341].

4.1.3. *Producers and Production Capacities*

The capacity for production of EVM or AEM copolymers was 215 000 t in 1996 according to IISRP [410]. It is not clear how many tonnes of elastomer grades are actually produced.

The most important *producers* of EVM and AEM solid rubbers are Bayer [Dormagen, Germany, trade name Levapren (EVM)] [412], Du Pont [Orange, Texas, trade names Elvax (EVM), Vamac (AEM)], and Exxon [Antwerpen, Belgium, trade name Escorene (EVM)].

4.1.4. *Toxicology*

EVM copolymers are physiologically harmless. They are licensed for contact with foods and correspond to recommendations of the BGVV (the former BGA) [411].

4.2. Epoxide Rubbers (CO, ECO, GECO, GPO)

Epoxide rubbers (designations according to ISO 1629) are derived from epichlorohydrin and from propylene oxide. The following epichlorohydrin elastomers are commercially available:

Epichlorohydrin Elastomers
CO. polychloromethyloxiran (epichlorohydrin elastomer) [24969-06-0]
ECO. ethylene oxide (oxiran – chloromethyl oxiran (epichlorohydrin) copolymer [24969-10-6]
GECO. epichlorohydrin – ethylene oxide – allyl glycidyl ether terpolymer [26587-37-1] (ASTM D 1418–90)
GCO. epichlorohydrin – allyl glycidyl ether copolymer [24969-09-3]

Propylene Oxide Elastomers
GPO. propylene oxide – allyl glycidyl ether copolymer [25104-27-2]. Propylene oxide elastomer is no longer commercially available.

Epichlorohydrin elastomers were first introduced in 1965 by B. F. Goodrich under licence from Hercules. GPO was introduced in developmental quantities (as Dyangen XP-139) by General Tire in 1964 and commercialized by Hercules (as Parel) in 1972.

All epoxide rubbers are specialty elastomers; their ozone and aging resistance is superior to general-purpose rubbers such as NR and SBR. *Epichlorohydrin rubbers* also have superior oil and fuel resistance, whereas *GPO* has excellent low-temperature flexibility and some oil resistance (comparable with CR). Its dynamic properties are similar to those of NR.

The chemistry of and markets for epichlorohydrin elastomers were reviewed in [413], [414]. A review of GPO is given in [415].

4.2.1. *Properties, Grades, and Applications*

Epichlorohydrin Rubber. The *epichlorohydrin homopolymer*, CO, has the structure $(CH_2–CH(CH_2–Cl)–O)_n$, i.e., it contains oxygen atoms in the polymer chain and 38 % chlorine as a substituent, which is responsible for its fuel resistance. The chlorine also imparts good flame retardance to the polymer. Epichlorohydrin homopolymer is outstanding in its low gas permeability and high ozone resistance, and is comparable to polyacrylate and NBR with medium acrylonitrile content in terms of oil resistance. The temperature flexibility of epochlorohydrin polymer is not satisfactory since its T_g is ≈ – 20 °C.

The 1 : 1 *epichlorohydrin – ethylene oxide copolymer*, ECO, $(CH_2CH(CH_2Cl)–O–CH_2–CH_2–O)_n$ contains 26 % chlorine. Its T_g is less than – 40 °C; hence its low-temperature properties are excellent. Epichlorohydrin – ethylene oxide copolymer is somewhat less fuel resistant than CO but still comparable in fuel resistance to a high-acrylonitrile NBR. The oil resistance of epichlorohydrin elastomers is intermediate between medium- and high-acrylonitrile NBR. ECO is less ozone resistant than CO and has a higher permeability to gas.

Epichlorohydrin polymers compounded with N 550 carbon black have enough electrical conductivity to dissipate static charges in belts, hoses, etc., since these rubbers are more polar than hydrocarbon-based rubbers.

Epichlorohydrin rubbers are subject to oxidative degradation that is initiated by hydroperoxide formation on the carbon adjacent to the oxygen in the chain. Oxidative degradation is counteracted by addition of protective agents such as nickel dithiocarbamates. With these agents the useful properties of CO are retained after 500 to 1000 h of air aging at 135 °C. Epichlorohydrin homopolymer (CO) retains its tensile strength better than ECO. After 1000 h at 135 °C CO retains its tensile strength while ECO loses 75 % of its strength. Epichlorohydrin rubber tends to soften in oil at elevated temperature (≥ 150 °C), or in gasoline containing hydroperoxides ("sour" gasoline). The softening has been attributed to scission of a carbon – oxygen bond according to the following mechanism [416]:

$$-CH(CH_2Cl)-CH_2-O-CH_2-CH_2- + RO\cdot(\cdot OH)$$

$$\rightarrow ROH(HOH) + -CH(CH_2Cl)-\dot{C}HOCH_2CH_2$$

$$-CH(CH_2Cl)-\dot{C}H-O-CH_2CH_2-$$

$$\rightarrow -CH(CH_2Cl)-CHO + \cdot CH_2-CH_2-$$

Metal dithiocarbamates promote this reaction because they catalyze the decomposition of hydroperoxides.

Epichlorohydrin rubber and ECO are not reactive enough to be vulcanized with sulfur, and require combinations of nucleophile, cross-linker, and acid acceptor, such as ethylene thiourea – lead oxide (1 : 5) as vulcanizing agents. GECO, containing reactive allyl glycidyl ether moieties, is cross-linkable with sulfur or peroxides as well as the cross-linkers used for CO and ECO [413]. When cross-linked by 2,4,6-trimercapto-s-triazine, GECO is lead free, is resistant to metal corrosion and heat softening, and has low compression set [417].

Uses. Epichlorohydrin rubbers are used in automotive radiator hoses, turbocharger hoses, and, if sour gasoline resistance is not a problem, fuel hoses and tubing. They are also used in suspension bushings, seals, gaskets, and coated fabrics, in rubber-covered rolls, and in oil-field specialties.

Propylene Oxide – Allyl Glycidyl Ether Copolymer. GPO is a copolymer of propylene oxide typically with 6 wt % allyl glycidyl ether. It has a T_g of –75 °C and a service temperature range of –60 °C to 135 °C. GPO is inherently ozone resistant.

Because of the reactive allyl glycidyl units the copolymer can be cross-linked by sulfur in the presence of accelerators such as tetramethylthiuram monosulfide (TMTM) and 2-mercaptobenzothiazole (MBT). Peroxides tend to degrade the polymer and are not suitable as cross-linking agents. The properties of GPO vulcanizates are generally similar to those of natural rubber or polychloroprene. The vulcanizates are moderately resistant to oils and aliphatic solvents.

Uses. GPO is principally used in engine and body mounts, because its dynamic characteristics are similar to those of NR over an even broader temperature range [419]. Possible applications include suspension bushings, dust seals, and boots.

4.2.2. *Basic Chemistry and Production Processes*

Epichlorohydrin Elastomers. The development of epichlorohydrin elastomers has been described [418]. Polymerization via a cationic coordination mechanism is carried out in solution in aliphatic or aromatic hydrocarbons, chlorinated hydrocarbons, or ether, with a catalyst formed by reacting R_3Al and water (thought to be $R_2Al–O–AlR_2$). Catalyst activity is improved by the addition of acetylacetone. Some combinations of organozinc and organomagnesium compounds, as well as other additives and chelating agents in combination with alkylaluminum compounds, are also effective catalysts. The polymer is produced in a continuous process using a back-mixed reactor. Polymerization proceeds at reasonable speed at room temperature but can be accelerated by raising the temperature to 50 °C.

Propylene Oxide – Allyl Glycidyl Elastomer. The production of GPO can be carried out in aliphatic, aromatic, or chlorinated hydrocarbon solution by using R_3Al – water – acetylacetone, diethylzinc – water, or complex cyanides as catalysts. Complete conversion and a uniform polymer with the composition of the original monomer feed are obtained.

4.2.3. *Producers and Production Capacities*

Producers of epoxide rubber are listed in Table 26 together with their production capacities.

Table 26. Producers, production capacities, and trade names of epoxide rubbers (based on data from International Institute of Synthetic Rubber Producers Inc.)

Producer (country)	Production capacity, t/a	Trade name
Zeon Chemicals (United States)	9 900	Hydrin H (CO)
		Hydrin C (ECO)
		Hydrin T (GECO)
Nippon Zeon (Japan)	1 500	Gechron 1000 (CO)
		Gechron 1100 (GCO)
		Gechron 2000 (ECO)
		Gechron 3100 (GECO)
Osaka Soda (Japan)	1 200	Epichlomer

4.3. Polynorbornene

Polynorbornene is the common name of polymers obtained by homopolymerization of bicyclo[2.2.1]hept-2-ene [498-66-8] called 2-norbornene. Since the 1940s this highly strained reactive molecule has been subjected to numerous polymerization studies applying many different types of catalysts [420]. 2-Norbornene polymerization can occur via two different modes: ring-opening metathesis polymerization and vinyl-type polymerization. Metathesis is mainly a reaction between two olefins, characterized by cleavage and reformation of carbon – carbon double bonds. With cyclic olefins, it becomes a ring-opening polymerization reaction [421], [422]. Vinyl-type polymerization maintains the cyclic structures. Basically four different polymeric structures can be obtained, depending on the type of catalyst or cocatalyst. Most frequently, a combination of two or three of these structures is observed.

In 1970, the French company CdF Chimie began intensive studies on the polymerization of 2-norbornene, which led to a commercial polynorbornene that has been produced on an industrial scale since 1976. This polymer possesses molecular structure **2** and is characterized by an unusually high molar mass (> 3×10^6 g/mol) and a glass transition temperature of 37 °C; therefore it can be regarded as an intermediate between elastomers and thermoplastics. However, it is highly compatible with plasticizers and acquires elastomeric properties by incorporation of these substances.

Polynorbornene is presently produced in France by Elf Atochem and developed worldwide in its main applications by Nippon Zeon, under the trade name Norsorex.

4.3.1. *Production of 2-Norbornene Monomer*

2-Norbornene is most commonly synthesized by Diels – Alder addition of cyclopentadiene (CPD) and ethylene. Cyclopentadiene is itself produced by cracking of dicyclopentadiene (DCPD) at > 160 °C. Dicyclopentadiene is extracted from the C_5 streams from naphtha steam cracking (⟶ Ethylene – Cracking Conditions, ⟶ Ethylene – Heat Requirements for Hydrocarbon Pyrolysis, ⟶ Ethylene – Commercial Cracking Yields, ⟶ Ethylene – Commercial Cracking Furnaces; ⟶ Resins, Synthetic). The addition reaction occurs without catalyst at high temperature and high pressure.

Because of the impurities contained in commercial DCPD (about 5 %) and the byproducts formed by reaction of 2-norbornene with the raw materials, a thorough purification of 2-norbornene is required after the synthesis step, in order to obtain a polymerizable monomer (purity > 99.7 %). Pure 2-norbornene is solid at room temperature (*mp* 47 °C) and must be protected from oxidation.

4.3.2. *Polymerization*

Commercial polynorbornene (Norsorex) is produced by a metathesis type of polymerization, catalyzed by a transition-metal salt [423]. The chemical structure of the polymer results essentially from a ring-opening polymerization, preserving one double bond per repeating unit with mainly *trans* configuration. According to the IUPAC system, its name is poly(1,3-cyclopentylenevinylene) [25038-76-0].

Polymerization is extremely rapid and highly exothermic. By application of a special technology the polynorbornene obtains a convoluted and porous structure. After cooling and drying, the polymer appears as a white, free-flowing, amorphous powder, with a grain size of < 0.8 mm and an apparent density of 0.3 g/cm^3. The porous structure and the presence of double bonds render polynorbornene very sensitive to oxidation. Therefore, a nonstaining antioxidant is added during its manufacture.

4.3.3. *Properties*

4.3.3.1. *Properties of Pure Polymer*

The chemical structure, the uncommonly high molar mass, and the unusual transition temperature are responsible for the unique properties of polynorbornene. Typical properties are given below:

Molar mass	> 3×10^6 g/mol
T_g	37 °C
Density	0.96 g/cm^3
Refractive index	1.534
Solubility parameter	19.8 MPa$^{1/2}$
Thermal conductivity	0.285 W m^{-1} K^{-1}

Dielectric constant (1 MHz)	2.5
Dissipation factor (1 MHz)	10^{-4}
Volume resistivity	$7\times10^{16}\ \Omega\cdot cm$

The thermal behavior of the product classifies it as a thermoplastic with a very low glass transition temperature. Polynorbornene is impossible to melt because of its high molar mass and decomposes at > 200 °C without real fluidization. The polymer exhibits a “shape memory effect” (it recovers its memorized shape when heated to more than 37 °C) [424]. Pure polynorbornene is used in only a few minor applications.

Polynorbornene has a very high affinity for liquid hydrocarbons, promoted by its porous structure. Pure polynorbornene is considered a highly efficient antipollutant because of its ability to absorb and gel usually ten times its weight of common hydrocarbons. Because of the compatibility of polynorbornene with extension oils that act as plasticizers, the transition temperature of the polynorbornene – oil mixture is lowered to – 60 °C, converting the plasticized polynorbornene into an elastomer. The presence of double bonds in the polymeric chain allows further vulcanization with common peroxides or sulfur vulcanization systems.

4.3.3.2. *Properties of Polynorbornene Rubbers (PNR)*

Polynorbornene rubbers are unique because of the high level of plasticizers and fillers that can be incorporated. Plasticizers can be applied at up to 500 parts per 100 parts of polymer; fillers, at up to 2000 parts. Most usual PNR compounds contain on average 20 % pure polynorbornene. This explains the prime importance of an appropriate selection of the compounding ingredients, both qualitatively and quantitatively. The properties of the resulting vulcanizates will thus vary over a wide range and can be “custom-tailored.”

Only some general physical and chemical properties are related strictly to the polymer itself. These can be summarized as follows: good aging and heat resistance (up to 90 °C), excellent mechanical strength, low compression set, and high compatibility with most other rubbers. Polynorbornene rubbers exhibit poor ozone resistance when unprotected; however, efficient protection is obtained by addition of antiozonants or a small amount of EPDM rubber.

Influence of the Plasticizer. The amount of plasticizer included determines the softness of the vulcanizate; unusually low hardness values down to 10 Shore A can be reached in combination with good mechanical properties. The type of plasticizer used affects the cold resistance, energy absorption capability, and compatibility with other rubbers. Figure 20 shows the variation of elasticity as a function of temperature for a given PNR compound in which only the type of oil used as plasticizer varies. This illustrates how the shock absorption ability can be adjusted; in this example a rebound between 5 and 60 % is obtained at room temperature. Table 27 shows the dependence of the cold resistance (brittle point) of the vulcanizates on the type and level of plasticizer.

Figure 20. Influence of oil type on rebound

a) Paraffinic oil; b) Naphthenic oil; c) Aromatic oil (high viscosity)

Table 27. Influence of plasticizer type on brittle point

Type	Level, phr				
Aromatic oil	180			160	
Naphthenic oil		180			180
Paraffinic oil			180	20	
Dioctyl adipate					40
Brittle point, °C	–30	–42	–49	–38	–52

Influence of Filler. All types of mineral fillers and carbon blacks can be used with PNR. The importance of their effect depends on their concentration in the rubber compound. The type of filler influences mainly physical properties such as strength, abrasion, and tear resistance; electrical properties; and dynamic damping properties. Table 28 lists the mechanical properties of a given PNR compound containing 200 parts of naphthenic oil and 200 parts of various fillers.

Table 28. Influence of filler type

Characteristic	Type of filler					
	Whiting	MT	SRF	GPF	FEF	HAF
Hardness, Shore A	28	35	43	53	57	61
Tensile strength, MPa	10.5	11.8	14.6	14.8	15.1	16.9
Elongation, %	525	507	369	322	276	268
Rebound at 20 °C, %	55	56	45	35	34	22.5

Figure 21 illustrates the dynamic damping behavior of PNR compounds filled with two different carbon blacks (SAF, MT) in comparison to the elastic natural rubber and the dampening chlorobutyl rubber.

Figure 21. Damping factor of some rubber compounds

a) Natural rubber; b) Norsorex plus MT; c) Chlorobutyl rubber; d) Norsorex plus SAF

Frequency: 125 Hz; Applied force: 10 N

4.3.4. ***Processing of PNR***

Both internal mixers and open mills can be used for PNR compounding. The equipment must be preheated at ca. 80 °C to avoid possible degradation of

the long polymeric chains at lower temperature due to mechanical rupture. The process always involves a preliminary absorption of oil (i.e., plasticizer) by the powdered polymer, so that it becomes an elastomeric material that can be submitted to shearing. For the production of very soft compounds, a masterbatch with a limited amount of oil (150 parts) is generally mixed first; the additional ingredients are introduced in a second mixing step. Subsequent processing is performed with common equipment in the rubber industry (⟶). The compound can also be prepared as a free-flowing dry blend in a high-speed powder blender. The dry blend may be extruded directly or injection molded.

4.3.5. *Uses*

PNR is a specialty elastomer, used mainly in applications where its unique properties are in demand. The most important developments are in the field of low-hardness solid parts and elastomers with tailored damping properties. These characteristics are exploited in very different industries such as the automotive, appliance, office equipment, and leisure industries for the production of molded or extruded goods such as seals, boots, damping pads, bumpers, rolls, and shoe insoles.

PNR is also used in blends with other elastomers to improve some of their characteristics such as green strength, hardness, or damping.

4.3.6. *Economic Aspects*

Worldwide production capacity of polynorbornene is presently 5000 t/a in the French plant of Elf Atochem (Carling). Consumption of pure PNR was about 1000 t in 1991, corresponding to about 5000 t of compounded elastomer.

4.3.7. *Toxicology*

Polynorbornene powder is nonmutagenic (Ames test) and nontoxic: acute oral toxicity for rats is 11 g/kg.

4.4. Polyoctenamers

In the ring-opening metathesis polymerization of cycloolefins, unsaturated polymers are formed — the so-called polyalkenamers [425] or polyalkenylenes [426] (both names are used in the literature and in *Chemical Abstracts)*. Only polynorborene (see Section Polynorbornene), polydicyclopentadiene, and polyoctenamers [28702-45-6] are produced on an industrial scale [427], [428]. At first, research on polyoctenamers concentrated on polymers rich in *cis* structures [429], [430]. However, for economic reasons an industrial breakthrough was achieved only with the *trans*-polyoctenamers [28730-09-8] [431].

4.4.1. *Production of Cyclooctene*

Cyclooctene [931-88-4] is obtained by partial hydrogenation of 1,5-cyclooctadiene [111-78-4]. Originally, the latter was formed as a byproduct in the synthesis of 1,5,9-cyclododecatriene, an intermediate produced on an industrial scale by Hüls AG, now Degussa AG [432]. Because of increasing demand for 1,5-cyclooctadiene the dimerization of butadiene, known since 1953 [433], [434], is also used for its production. Instead of the original Reppe-type catalysts, modified Ziegler – Natta catalysts with zerovalent nickel are now used for dimerization [435], which give 1,5-cyclooctadiene with complete conversion of starting material and high selectivity at elevated temperature. The crude product is separated from byproducts and catalyst residue by flash evaporation. The purity of this intermediate is > 99 %.

The selectivity of the hydrogenation of 1,5-cyclooctadiene to cyclooctene is slightly less than 100 % when commercial heterogeneous catalysts are used. With precise temperature control and hydrogen metering a specially developed hydrogenation catalyst gives complete selectivity. A small degree of overhydrogenation to cyclooctane must be put up with. Otherwise, traces of 1,5-diene can remain in the product that may hinder the sensitive polymerization process, because the 1,5-diene tends toward double-bond isomerization to 1,3-cyclooctadiene. Especially the latter acts as a strong catalyst poison [436-438]. The final product with the purity necessary for polymerization contains 95 – 97 % cyclooctene; the remainder is essentially cyclooctane.

4.4.2. *Polymerization*

In the first ring-opening polymerization of cyclooctene in 1965 by NATTA et al., tungsten or molybdenum salts in combination with organoaluminum compounds were used as catalysts [439]. In 1967, CALDERON et al., succeeded in improving polymerization conditions by using the catalyst system WCl_6 – $EtAlCl_2$ – EtOH. At the same time they reported an extractable oligomer fraction in the polymerization of cyclooctene and other cycloolefins. They concluded that the process was entropy controlled because of the low heat of reaction.

Following that time, many other articles on the metathesis polymerization of cycloolefins, including cyclooctene, have been published. Most of the original work is summarized in three monographs [440-442] and many review articles [429], [430], [443-448].

The mechanism of ring opening during polymerization is still being disputed. The nature of the metal complex formed as a transition state before ring opening, which initiates the actual polymerization, is not certain.

One proposal is that two monomer molecules form a bisolefin – metal complex (A) that undergoes ring expansion to give a cyclic diolefin with double the number of ring members. Since the double bonds of this dimer have the same reactivity as those of the monomer, the ring-expanding metathesis can continue until macrocyclic polymers are obtained.

The alternative theory states that a metal carbene – olefin complex (B) is formed, in which only three carbon atoms participate in the reaction with the metal atom. This leads primarily to linear polymers. The formation of cyclic oligomers is explained by backbiting. This transition state is the preferred model. It is in good agreement with the polymerization pathway, which is assumed to be a chain reaction. The formation of macrocyclic polymers is less easily explained with this model. Since macrocycles with molar masses up to 100 000 g/mol have been detected in polyoctenamers [449], [450], transition state (A) cannot be ruled out completely.

Both theories have advantages and disadvantages. Many questions remain unanswered because of the complex nature of the reaction. All the reactions taking place — for example, stereospecific reactions, oligomerization and degradation of linear and cyclic molecules, and reactions regulating the molar mass — are equilibrium reactions. They are as yet not completely understood theoretically. A detailed discussion of the mechanism of the ring opening and the propagation reaction is given in [442]. However, the polymerization can be controlled reproducibly to a great extent by catalyst composition and reaction conditions.

On an industrial scale, polymerization is carried out in hexane. High-purity monomers and anhydrous conditions are essential. A tungsten-based, modified Calderon catalyst is used. The polymerization is carried out adiabatically, goes to complete conversion, and gives almost 100 % yield. The workup involves flash evaporation of the solvent with subsequent recycling. The final product is filtered in the melt, pelletized after cooling, and packed in bags. Its purity is

> 99.5 %. The content of monomer (mainly cyclooctane) and low molar mass oligomers is very small.

4.4.3. *Properties*

Polyoctenamers have been produced over wide ranges of both molar mass and *cis : trans* ratios of double bonds [429], [451], [442]. All products exhibit bimodal molar mass distributions, which are typical for metathesis polymerization, with the first maximum at low molar mass oligomers. The crystallinity of polyoctenamers depends strongly on their microstructure (i.e., the ratio of *cis : trans* double bonds). The double bonds can be arranged in sequences, and crystallites with defined melting temperatures are then formed. With respect to the crystallinity the effect of the *trans* double bonds is more pronounced than that of the *cis* double bonds. Recrystallization from the melt occurs within seconds. This effect is very important in certain applications involving rubber processing.

Depending on the reaction mechanism, linear, unbranched polymers with an ideal polymethylene structure are formed in the polymerization, in addition to macrocycles. A double bond occurs at every eighth carbon atom of the chain or macrocycle. This explains the high chain mobility and the low glass transition temperature T_g.

Two polyoctenamer grades are available commercially from Degussa AG under the trade name Vestenamer. The low molar mass and crystallinity are chosen specifically so that they give advantages in rubber processing because of their low melt viscosity. In comparison to common baled rubbers the handling of polyoctenamers is simplified because they are delivered as pellets. Data for these two Vestenamer grades are given in Table 29.

Table 29. Typical polymer properties of Vestenamer 8012 and 6213

Property	Vestenamer grade	
	8012	6213
Molar mass, g/mol	70 000	90 000
Glass transition temperature T_g, °C	–65	–75
Crystallinity (at 23 °C), %	30	12
mp, °C	54	< 36
Start of thermal decomposition, °C	275	250
Ratio of *trans : cis* double bonds, %	80 : 20	60 : 40
Mooney viscosity ML (1 + 4) (at 100 °C)	< 10	< 10
Viscosity number *J* (at 23 °C), mL/g	120	130
Density, g/cm^3	0.91	0.89

4.4.4. *Vulcanization, Processing, and Applications*

The molar mass of Vestenamer is kept intentionally low for a rubber. Because of the thermoplasticity the viscosity in the molten state is unusually low compared to other solid rubbers: The Mooney value ML (1 + 4) at 100 °C is only 5 – 8. Because of its high degree of unsaturation, Vestenamer can be vulcanized with all the cross-linking agents commonly used in the rubber industry (e.g., sulfur, sulfur donors and accelerators, peroxides, and vulcanization resins). Therefore, Vestenamer has two functions when used as a blend component in rubber compounds, in which 5 to 20 parts of the basic rubber are generally replaced. Because of its low viscosity, Vestenamer acts as a *plasticizer* or processing agent in compounding and molding. However, after vulcanization it is *cross-linked* like all other rubbers, completely incorporated into the network, and can no longer be extracted. This means lower overall energy consumption for the mixing process, easier filler incorporation, better filler dispersion, and a smaller temperature increase during mixing. In extrusion processes the mass pressure and die swell are decreased, and the surface finish of the extrudates (e.g., profiles or tubing) is improved. The high rate of crystallization of Vestenamer leads to a significantly higher green strength of the compounds. Thus the rigidity and dimensional stability of extrudates, which are stored before vulcanization, are increased markedly. Examples are tire bead and apex compounds, profiles, and braided hoses. Because of the improved flow properties of the mixtures, the mold-filling process can be improved and shortened in the production of molded articles, and complicated mold geometries are cleanly produced. Because of the rapid recrystallization of Vestenamer 8012 the anisotropy of the calender shrinkage — i.e., the different shrinkage in the longitudinal and transverse directions — is significantly reduced. Even very thin sheets can therefore be calendered without defects. The tack of the compounds is reduced due to the completely unbranched polyoctenamer molecules in combination with their crystallinity. (This is a disadvantage in NR compounds for tire production, but an advantage in CR compounds [451-454].)

The *vulcanizate* properties of rubber – polyoctenamer blends are barely affected compared to compounds without Vestenamer. Tensile strength and tear resistance are decreased somewhat because of the low molar mass of the polyoctenamer. The elongation at break decreases and the modulus increases. The hardness is also increased because the residual crystallinity is noticeable after cross-linking. The ozone resistance is not affected. In blends of polar and nonpolar (NBR – EPDM) or emulsion and solution rubbers (NR – BR), addition of small quantities of Vestenamer (5 – 10 phr) clearly increases dispersion of the otherwise mutually not very compatible rubbers, and processing is thus improved.

Over the years new applications have been commercialized, some of them outside traditional rubber processing, e.g., in the modification of plastics. The dynamic properties of natural rubber compounds are improved on blending with Vestenamer, and reversion is suppressed at the same time [455]. These results open up interesting possibilities for tire compounding and production. Interest is also increasing in the use of Vestenamer — blended with other rubbers or as the only rubber component — for the production of extremely hard but nevertheless readily processible tire apex compounds or golf balls [456].

In tire compounding blending with Vestenamer lowers the shrinkage of inner liner compounds and offers the possibility to partly dispense with the expensive silane filler activator in silica-filled tire treads [462].

The pronounced thermoplasticity and low melting point permit the use of Vestenamer as a carrier material for filler batches. The filler incorporation by Vestenamer is high, and the rapid recrystallization from the melt allows granulation of the batches. Vestamer is often used in combination with other carrier materials to inhibit their undesired tackiness. Batches using Vestenamer as carrier material for accelerators, peroxides, very fine powders, or even liquid rubber chemicals, are commercialized.

Vestenamer – oil mixtures are used as coating and binding agents for ground rubber waste powder [457]. The importance of this process for reduction of the large amounts of waste rubber was met with increasing interest during the last years, because recycling of waste rubber is technically difficult.

Based on the experience with rubber recycling, Vestenamer is since 1999 used in rubberized asphalt [458]. Crumb rubber (ground tire rubber, GTR) enhances the durability and performance of asphalt concrete pavements. But the hot GTR-asphalt mix exhibits high tackiness, which causes problems in processing and handling (separation of GTR in the terminal blending tank, sticking to the rolling equipment). Addition of a small amount of Vestenamer (about 0.5 %) successfully overcomes these problems, and increases the PG (Performance Graded) ratings of the asphalt. Vestenamer functions as reactive modifier and forms a uniform, low-tack, rubber-like composite from GTR and asphalt [459, 460]. This patented mixing process [461] reduces the costs of paving. A number of test roads demonstrate the high quality of pavements with rubberized asphalt containing Vestenamer.

4.4.5. *Economic Aspects*

Detailed economic and ecological analyses of the metathesis processes used industrially show clearly their advantages and disadvantages [436]. Analysis makes clear why polyoctenamers can be produced on a commercial scale, unlike polypentenamers, which were intended for very similar applications.

Vestenamer production began in a pilot plant in 1980, and in 1989 a large plant with a capacity of 10 000 – 12 000 t/a was put in operation. Its nominal capacity was reduced to 3000 t/a after Hüls AG had finished their activities in the rubber business by December 31, 1994.

In 2002, 38 % of the Vestenamer produced were sold in Germany, 34 % in the rest of Europe, 23 % in both Americas, and 5 % in Asia. The following quantities of Vestenamer were consumed in different areas of the rubber industry:

Tires	44 %
Extrudates	18 %
Molded articles	7 %
Calendered articles, rubber soles, roll covers	4 %
Recycling	12 %
Custom compounding	5 %
Other	10 %

Vestenamer is used predominantly in blends with the following rubbers: NR, SBR, EPDM, NBR, CR, CSM, and pre-cross-linked butyl rubber.

4.4.6. *Toxicology*

Vestenamer and its precursors have been thoroughly investigated with regard to their toxicology.

1,5-Cyclooctadiene has an LD_{50} of 1900 mg/kg in rats (oral) and of > 10 000 mg/kg in rabbits (dermal). It has a slight irritant effect on the skin (OECD test 404), but shows no sensitizing effect in the corresponding test according to Magnusson and Kligman. It is not irritating to the eyes or mucous membranes (OECD test 405).

Cyclooctene has an LD_{50} of 4550 mg/kg in rats (oral) and of > 10 000 mg/kg in rabbits (dermal) and a slight irritant effect on the skin (OECD test 404). It shows no sensitizing effect in the corresponding test according to Magnusson and Kligman, and is not irritating to the eyes or mucous membranes (OECD test 405).

Trans-Polyoctenamer has an LD_{50} of > 12 500 mg/kg in rats (oral) and has no irritating effect on the skin or on rabbit eyes. In rats, 90-d oral administration at concentrations up to 4000 mg/kg body weight did not result in any toxic effects. Vestenamer showed no mutagenic effects in the Ames test (in vitro) on *Salmonella typhimurium* and the micronucleus test (in vivo) on mice

The Scientific Committee on Food of the European Commission evaluated cyclooctene for food contact and approved it for use in aqueous foodstuffs (restriction: specific migration limit (SML) 0.05 mg/kg). Cyclooctene has been added to Section A of the Positive List for Monomers of the EU-Plastics Directive 90/128/EEC (6th Amendment). Thus Vestenamer can be used safely in contact with aqueous foodstuffs (but not in contact with alcoholic and fatty foods).

5. Synthesis by Polyaddition, Polycondensation, and Other Mechanisms

Jürgen Ackermann, Dieter Wrobel, Uwe Hoffmann, Hans Dieter Thomas, Rüdiger Engehausen, Stephen D. Pask

5.1. Silicone Rubber

Silicone elastomers (Q) form the most important class of rubber composed of repeating inorganic Si–O instead of C–C units in the polymer chain. Silicone polymers can bear various organic substituents on silicon.

According to ASTM 1418, the initial letters of substituents X and Y (methyl, phenyl, vinyl, and fluoralkyl) are used before the letter Q to differentiate among the individual Q grades (MQ, VMQ, PVMQ, FMQ, FVMQ). ISO 1629 uses the same letters but in a different order (MVQ, PMVQ, FMVQ).

Pure polydimethylsiloxanes with cross-linkable vinyl or SiOH groups as side- or end groups are by far the most important products of the silicone industry. Different substitution of siloxy groups and degrees of polymer chain lengths give rise to an extraordinary number of products and a broad application range [463]. Peroxide -cured silicone rubbers (hot vulcanization, HV) have been marketed since 1944, shortly after the industrial production of silicones began in 1939 [464]. The low strength of unfilled silicone elastomers was improved by the introduction of “white soot” (fumed or pyrogenic silica in 1942) as a reinforcing filler and by incorporation of cross-linkable vinyl groups into the polymer.

Low-viscosity two-component rubbers, which can be cured at room temperature (room temperature vulcanization, RTV), followed in 1954, and in 1958 the first one-component RTV rubber for sealants. In 1976 liquid silicone rubbers (LSR) appeared in the market.

5.1.1. *Properties, Grades, and Applications*

Commercial silicone rubbers are divided into four main groups depending on their applications and viscosities. These can, in turn, be differentiated according to cross-linking mechanism and polymer type [465], [466].

1. Solid rubbers [(HV = hot vulcanization rubber)]: VMQ, FVMQ, PVMQ
2. Liquid silicone rubbers (LSR, two-component): VMQ, FVMQ
3. Molding (casting) compounds (RTV-2 = two-component room temperature vulcanization): MQ, VMQ, FVMQ, PVMQ
4. Sealants (RTV-1 = one-component room temperature vulcanization): MQ, PMQ, FMQ

Solid silicone rubbers are marketed mostly as HV base compounds without peroxide. *Liquid Silicone* Rubbers are sold exclusively as two (A and B) components, which are formulated ready for use. For *casting* or *molding compounds* as well as *sealants* silicone producers also supply raw materials.

HV rubbers are kneadable, noncreeping compounds mostly with a yield point. Their Mooney viscosities at room temperature are comparable to those of other rubbers at 80 – 140 °C. The viscosities of the other silicone rubbers are so low that they can be pumped with commercial metering pumps (piston type) or are free-flowing. Unlike the other rubbers one-component RTV compounds are formulated to exhibit a strong yield point, which hinders undesired flow out of vertical joints [466]. The different viscosity ranges for Q rubbers at a shearing rate $\dot{\gamma} = 1\ s^{-1}$ are as follows:

HV	40 000 – 200 000 Pa · s (Mooney: 20 – 100)
LSR	100 – 5 000 Pa · s
RTV-2	10 – 50 Pa · s

RTV-1	40 – 100 Pa · s

The Q elastomers made from solid HV or liquid silicone rubbers have better mechanical properties than one- or two-component RTV compounds (see Table 30) [467], [468]. HV and LSR are mainly used for production of heat-resistant molded or extruded articles.

Table 30. Mechanical properties of Q rubbers

	HV	LSR	RTV-2	RTV-1
Hardness, Shore A	20 – 90	20 – 80	0 – 90	15 – 25
Tensile strength, MPa	6 – 12	6 – 10	0.5 – 6	1 – 3
Tear ASTM 624B, N/mm	10 – 45	15 – 50	10 – 20	3 – 8

One-component RTV sealants are characterized by good *adhesion* to a wide variety of surfaces. The low tensile strength of these rubbers inhibits their application in the fabrication of molded or extruded articles.

Two-component RTV rubbers used for casting and molding applications have low *viscosities* and undergo vulcanization at room temperature.

The Q elastomers can be characterized by the following properties in comparison with other synthetic rubbers:

1. Higher low-temperature flexibility
2. Higher oxidation and hot air resistance
3. Higher UV and ozone resistance
4. Very high gas permeability
5. High transparency
6. High electrical resistivity
7. Low surface tension
8. Low temperature dependence of mechanical properties
9. Physiological compatibility

The relaxation and elastic properties of silicone rubbers are nearly constant over a broad temperature range of – 45 to 200 °C [470]. Rubbers containing more than 4 mol % diphenyl- or methylphenylsiloxy groups (PVMQ) have an equilibrium melting point T_m of – 70 °C instead of – 45 °C (brittleness point – 105 °C instead of – 55 °C) while the glass transition temperature T_g remains unchanged at – 120 °C [471]. The transparency, the resistance to oxidation and irradiation are also increased by phenyl groups. The introduction of additional siloxy groups with polar substituents, such as CN- or $F_3CC_2H_4$-groups, into the polymer chain reduces swelling in nonpolar solvents, e.g., aliphatic or aromatic fuel [472].

Oxides or complexes of Ti, Zr, Mn, or Ce are used as stabilizers against aging by hot air, preventing oxidation of methyl and alkylene groups under formation of additional cross-links. Exposure to acids (oxidized oils), amines, or steam leads to depolymerization. The action can be suppressed by alkaline earth oxide, carbonate or silicate fillers. VMQ exhibits 50 % residual elongation even after aging under extreme conditions, i.e., after 60 d at 250 °C or 21 d at 300 °C in air, 30 d at 160 °C in steam, 2000 h at 150 °C in ASTM 2 oil. For silicone foams, see ⟶ Foamed Plastics – Silicone (SI) Foams.

Elastomer blends of VMQ with other peroxide curable polymers can be formulated. Blends with other rubbers, tetrafluoroethylene – hexafluoropropylene (FKM) or ethylene – propylene – diene (EPDM) and others are described in the patent literature and are produced commercially [473], [474]. A large number of siloxane block copolymers with thermoplastic hard segments such as polycarbonate, polysulfone, polyimide, or silarlylene are known. They exhibit properties of thermoplastic elastomers [468], [469], [475].

Applications. Uses of different silicone rubbers as a function of their properties are listed in Table 31. Typical articles produced from silicone rubber include: cable insulations, seals and tubing for food and processing equipment, key(board)pads, baby nipples, and pacifiers, shaft seals, anode caps, spark plug boots, membranes, implants, drug release carriers, electronic encapsulation, photocopier rolls, molds for replication of art or denture, window or sanitary seals, adhesives, adhesive controlled release coatings for paper, waterproof and thermal-shielding [465], [476], [477].

Table 31. Properties of Q rubbers that determine application

Grade	Processing	Main property
HV	extrusion	toughness and relaxation –105 to 300 °C
HV/LSR	molded articles	toughness and relaxation – 105 to 300 °C, short cycle times
HV/RTV-2	foam	heat insulation, flame resistance
RTV-1	joints	weathering resistance, adhesion
LSR/RTV-2	coating	surface tension, adhesion
RTV-2	castings, sealing	room temperature vulcanizaton, flow properties
	reproduction	room temperature vulcanization, electrical insulation
	gels	low hardness, damping

5.1.2. *Production Process and Basic Chemistry*

The starting materials for the production of silicone rubbers are linear silicone polymers with reactive SiOH or vinyl end groups. For production of silicone polymers, see ⟶ Silicon Compounds, Organic.

Rubber Compositions. The compositions of different silicone rubbers are given in Table 32. The silicone polymers differ in the lengths of their SiO chain, functionalities, and vinyl or SiOH contents. Fumed or precipitated silicas are used almost exclusively as reinforcing filler in silicone rubber. As exception carbon black is used in electrically conductive rubbers. The performance of silica fillers can be improved by adding hydrophobizing agents acting either before or during the mixing process [478]. These process aids, sometimes incorrectly called plasticizers, are based on either polysiloxanediols, disilazanes or alkoxysilanes [479], [480]. Process aids lower the structural viscosity and prevent the crepe hardening (increase in viscosity during storage) of the compound while simultaneously drying the filler [481]. Quartz powder, diatomaceous earth, micas, talcs, chalks, powdered alkaline earth oxides and of Fe, Ti or Al can be used as inert fillers.

Table 32. Composition of silicone rubbers (in parts by weight per 100 parts by weight of Q polymer)

Component	RTV-1	RTV-2	LSR	HV
Polymer chain length	1000	100 – 1000	500 – 1000	6000
Functionality	SiOH	SiOH/Si vinyl	Si vinyl	Si vinyl
Silica	5 – 10	0 – 30	0 – 40	0 – 75
Vinyl resin		0 – 30	0 – 30	0 – 20
Process aid		0 – 10	0 – 10	0 – 15
Plasticizer	0 – 30	0 – 20		
Inert filler	0 – 100	0 – 100	0 – 50	0 – 300
Cross-linker				
1	$RSi(OR)_3$	$Si(OR)_4$	SiH – siloxane	
2		SiH – siloxane		SiH – siloxane
Catalyst				
1	Sn	Sn	Pt	peroxide
2		Pt		Pt

Moisture-cured one-component RTV compounds are formulated as ready-for-use rubbers. Silanes, such as methyltriacetoxysilane, which undergo hydrolysis upon contact with ambient moisture, act as cross-linker. Fumed silicas (partially hydrophobized) with low water content and chalks coated with stearic acid are common fillers. The cross-linking reaction is catalyzed by a tin compound (e.g., dibutyltin dilaurate). Nonfunctional polydimethylsiloxane fluids are used as plasticizers [482].

Two component RTV compounds are based on polymers with SiOH or vinyl groups and little or no reinforcing filler to achieve lowest viscosities possible. The SiOH containing polymers are cured by condensation, those containing vinyl groups by hydrosilation. Q-resins with vinyl groups enable improved cross-linking density and reinforcement without silica filler. These resins are common in hydrosilation -cured, low viscosity RTV-2 compounds [483]. The formulations of different two compound RTV systems are given in Table 33.

Table 33. Formulation of the two-component systems RTV-2 and LSR *

Component	Condensation cross-linking		Addition cross-linking	
	A component	B component	A component	B component
SiOH polymer	X			
SiVi polymer **			X	X
Filler	(X)		(X)	(X)
SiVi resin **			(X)	(X)
$Si(OR)_4$ cross-linker		X		
Water		X		
SiH cross-linker				X
Sn – Ti catalyst		X		
Pt catalyst			X	
Inhibitor				X

* x = substance is contained in component; (x) = substance that can be optionally incorporated.
** Silicone polymer containing vinyl groups.

Production Process. Solid HV-rubber is produced on roll mills, in kneaders, or in screw mixers [484], [485]. In contrast to other synthetic rubbers silicone rubber compounds are not prone to significant shear heating (heat-build-up) or polymer degradation because of their low viscosity. VMQ rubbers can be heated up to 180 °C to render the filler hydrophobic (by condensation of the process aids with the silanol groups of the filler surface) [480], [485]. Transparent or opaque “basic compounds” are obtained, which are optionally mixed with inert fillers, stabilizers, pigments, and finally with peroxides at 20 – 120 °C on roll mills or in kneaders and extruders.

The *liquid silicone rubbers* RTV-1 and RTV-2 can be formulated in mixers of the coating and paste industry [486]. Planetary mixers and dissolvers are generally used, but kneaders and screw extruders are also suitable. The mixing processes must be carried out under an inert gas because of the moisture sensitivity and at higher temperatures due to danger of ignition of low boiling ingredients.

Vulcanization and Cross-Linking Reactions.
Peroxide Cure. Radical cross-linking of pure methylsilicone rubbers with peroxides leads to a low cross-link density. Vinylsiloxanes are considerable more reactive to give improved cross-link density. Reaction of methyl or vinyl groups with the peroxide initiator generates propene, butene, and a few ethylene bridges [487].

Alkyl- or aroyl peroxides such as dicumyl peroxide, 2,5-dimethyl-2,5-bis(*tert*-butylperoxy) hexane, or bis(2,4-dichlorbenzoyl) peroxide as well as bis(4-methylbenzoyl) peroxide are used as catalysts [488].

Curing by Hydrosilation. Cross-linking by hydrosilation generates exclusively ethylene bridges. In contrast to the peroxide-induced cure no decomposition products are formed. The curing reaction is catalyzed by 5 – 150 ppm platinum as platinum salts, or Pt(0)-vinylsiloxanes, Pt(0)-olefin, or Pt(0)-phosphine complexes.

$$\equiv Si-CH=CH_2 + H-Si\equiv \xrightarrow{Pt} \equiv Si-CH_2-CH_2-Si\equiv$$

SiH – siloxanes of the formula $RMe_2SiO-(Me_2SiO)_n-(MeHSiO)_m-SiMe_2R$ (where R is Me or H) serve as cross-linking agents. Cross-linking agents are applied in concentrations of 0.5 – 15 wt %. To extend the cure time at room temperature up to several days, inhibitors such as 2-methyl-3-butyn-2-ol, 1-ethynylcyclohexanol, vinylsiloxane, amines, or ketones (0.01 – 0.3 wt %) are used in hydrosilation -cured rubbers [489], [490].

Curing by Condensation. Polyfunctional silanes are the most common cross-linkers in rubber systems cured by condensation reactions. *Two-component*

systems contain alkoxysilanes, such as tetraethoxysilane. *One-component systems* also use other silanes such as methyltrimethoxy-, methyl- or ethyltriacetoxy-, methyltris(butanone oxime)-, or methylethoxybis(*N*-methylbenzamide)silane. These silanes react with the SiOH-terminated polymers to form prepolymers which undergo further cross-linking in the presence of moisture. The condensation reaction produces alcohols, oximes, amides, or acids as byproducts. *One-component RTV* compounding involves the formation to a prepolymer endstopped by cross-linker [482], [486]. The condensation reactions are catalyzed by tin dicarboxylates or titanium chelates added at 0.2 – 1 %. The rate of cross-linking of the individual systems can be adjusted within wide ranges.

Rubbers that are cross-linked with *peroxides* have a cure rate determined by the decomposition rate of the peroxide. In *hydrosilation* the cure rate is controlled by the quantity of the inhibitors (alkynols), SiH-cross-linker and the platinum catalyst.

Condensation RTV systems can be modified in viscosity and elongation by the choice of cross-linking agent and the length and functionality of polymer chain. The cure rate of one-component *sealant rubbers* is mainly governed by the diffusion rate of moisture from the surface through the bulk of the material. The vulcanization properties of different Q rubbers are listed in Table 34.

Table 34. Vulcanization properties of Q rubbers

	Pot life, min	Vulcanization temperature, °C	Vulcanization time, min
HV	> 43 200	120 – 200	1 – 2
LSR	> 4320	160 – 200	0.15 – 1
RTV-2 condensation	30 – 120	25 – 40	3 – 1440
RTV-2 hydrosilation	1 – 3	25 – 80	3 – 1440
RTV-1	5 – 25 *	25	1.4 **

* Skin formation.
** µm/min.

Molded articles made of solid or liquid silicone rubbers are mostly subjected to postcuring at 200 °C (2 – 6 h) to remove peroxide decomposition products as well as other volatile components (siloxanes) and to improve (lower) the compression set.

Vulcanization Process. Solid HV-rubbers are vulcanized using common feeding and molding equipment. Machines involved are extruders, transfer molds, and screw conveyors, but also injection molding machines. Press molds can be filled manually either with sheets, strips, or granulates. Curing can be pressureless (hot air) for extrudates or under pressure in heated molds [491], [492].

Extruded articles (profiles, tubing) are cured using bisaroylperoxides [e.g., bis(2,4-dichlorbenzoyl) peroxide] or by hydrosilation. Alkylperoxides (e.g., dicumyl peroxide) which decompose at higher temperatures, are only suitable for press molding.

Liquid silicone rubbers (A and B components) are effectively conveyed by means of metering pumps in a 1 : 1 ratio (+ color paste) first through a static mixer and then into the injection molding machine. Vulcanization occurs in the heated mold. Cold-runner technology is established to reduce loss of material [493].

Casting and molding compounds are stirred with the cross-linking agent in the ratio 1 : 8 to 1 : 10 and are cross-linked at room temperature or slightly above. Dental molding compounds are dosed from double cartridges (dispensing gun) via a static mixer, or the individual components are kneaded together.

RTV-1 rubbers can be extruded out of cartridges with dispensing guns or from drums with appropriate equipment. RTV-1 rubbers cure on contact with atmospheric moisture.

Recycling and Environmental Aspects. Recycling of silicone implies the separate collection of used silicone articles. Silicone elastomers can be reused in limited quantities as rubber powder or reclaims (partially depolymerized by steam hydrolysis). Another way is depolymerization of the Q elastomers to give distillable cyclosiloxanes. This can be carried out by using strong acids (concentrated sulfuric acid), bases (amines), or high temperature. The cyclosiloxanes can be introduced again as raw materials for the production of selected Q polymers (⟶ Silicones) [494]. Toxicological and environmental aspects of siloxanes are described elsewhere (⟶ Silicon Compounds, Organic).

5.1.3. *Producers and Markets*

The producers of VMQ rubber and compounds are listed below in alphabetical order together with the corresponding trade names:

Bayer (Leverkusen, Germany)	Silopren
Chemkomb. Dankow (Lipezk, CIS)	
Chimprom (Cheboksary, Gorki CIS)	
Dow Corning (Midland, MI, United States)	Silastic
General Electric (Waterford, NY, United States)	Blensil, GE-Sil
Sivento (Nünchritz, Germany)	Sivento
Inkos (Retkino, CIS)	
Kasan (Kasan, Tataric Republic CIS)	
Rhône Poulenc (St. Fons, France)	Rhodorsil
Saporoshki Sawod (Saparoshje, Ukraine CIS)	Kremni Polimer
Shinetsu (Isoke, Japan)	KE, Sylon
Toshiba (Ota, Japan)	TSE
Toray (Chiba, Japan)	SH
OSi Specialties Witco (Sisterville, WV, United States)	Sag, Silwet
Usolje (Irkutsk, CIS)	
Wacker (Burghausen, Germany)	Elastosil

The market shares of different VMQ rubbers in the Western world are given in Table 35. A breakdown by application of hot vulcanization rubber according to end-users (% of total) is given in the following:

Electrical industry	30
Automotive	20

Medicine – foods technology	20
Photocopier rolls	5
Construction	10
Others	15

Table 35. VMQ rubbers and their markets in 1996 (t)

	Western Europe	Japan	United States	Rest of world
HV	20 000	18 000	34 000	33 000
LSR	5 400	800	3 400	2 400
RTV 2K	7 000	5 100	7 500	3 400
RTV 1K	100 000	20 000	70 000	50 000

5.2. Polyurethane Rubber (see also ⟶ Polyurethanes)

Properties, Grades, and Applications. Millable polyurethane rubbers that can be processed by the methods of the rubber industry are a special group of polyurethane elastomers. Of greater market importance is the largest group, the thermoplastically processible polyurethane elastomers (see Chap. Thermoplastic Elastomers; see ⟶ Thermoplastic Elastomers), and the polyurethane elastomers produced by casting (⟶ Polyurethanes – Cast Elastomers) [495-498].

Vulcanizates from polyurethane rubber are characterized by their high toughness, high abrasion resistance, good oil resistance, and excellent ozone and UV resistance. Depending on the curing method, they have a high elasticity even at great hardness (diisocyanate cross-linking) or very low gas permeability (peroxide cross-linking) [499], [500]. Their hardness ranges from ca. 50 Shore A to 70 Shore D. The products are available on the market as blocks or pellets. Their Mooney viscosity varies between 20 and 60 (ML 1+4, 100 °C).

The differences in properties of the vulcanizates arise from the choice of *raw materials*. Polyurethane rubber is produced according to the principle of diisocyanate polyaddition, discovered in 1937 by OTTO BAYER. Linear macromolecules can be built up by addition of diisocyanates to dihydroxy compounds [501]. The *dihydroxy monomers* are long-chain compounds, which can be polyester- or polyetherpolyols. Thus polyesterurethanes and polyetherurethanes can be made. To a great extent, the polyols determine the elasticity, low-temperature flexibility, resistance to hydrolysis, and swelling behavior of the rubber. The cross-linking system also influences the properties considerably. Polyurethanes can be cross-linked with diisocyanate, peroxide, or sulfur [496], [499], [502-504].

Diisocyanate cross-linking, which requires the use of a suitable polymer with free hydroxyl groups, gives vulcanizates with a high elasticity, even at hardness levels up to ca. 70 Shore D [499], [502], [504]. *Peroxide cross-linking* generally confers excellent compression set and leads to vulcanizates with improved aging properties [503], [504]. Because of the accelerator systems necessary for *sulfur cross-linking*, which have unfavorable effects on the polyurethane backbone, sulfur cross-linking gives vulcanizates with only moderate aging resistance [497], [501].

Compounding takes place according to the normal guidelines of the rubber industry. Reinforcing carbon blacks are the preferred fillers [502]. The use of a hydrolysis inhibitor is generally recommended for polyesterurethanes [505-508].

The maximum service temperature for peroxidically cross-linked vulcanizates is ca. 125 °C. The material may be used up to ca. 150 °C for a short period [499], [502], [509]. Because of their chemical nature, vulcanizates from polyurethane rubber are attacked under the long-term action of hydrolyzing media (e.g., acid or base, hot water, and steam). This applies particularly to polyester-based products [500], [505], [506], [509]. However, compared to the polyether-based products, which are more resistant to hydrolysis, polyester-based vulcanizates exhibit greater resistance to organic solvents and oils.

The *glass transition temperatures* are in the range – 10 to – 40 °C; the *brittleness temperatures* are significantly lower for certain elastomers (less than – 70 °C) [500].

Uses. Typical uses of polyurethane rubber are wipers, driving belts, ejection springs, diaphragms in suspension systems, bushings, seals, rubber – metal parts, couplings, sleeves, matrices for the ceramics industry, membranes, engine mountings, wheel coverings, grinding discs, and roller coverings [510].

Production Processes and Basic Chemistry. Unlike polymerization and polycondensation, the basis of polyurethane chemistry is polyaddition. Here urethane bonds are formed by bonding diisocyanates to diols. To obtain products that can be milled and are stable to storage, a molar ratio of the diisocyanate component to the diol component of < 1 is used [495-497].

Polyesters or polyethers with a molar mass of ca. 1000 to 2000 g/mol are used as the diols; examples are polyadipates or poly-C_4-ethers. The preferred diisocyanates are toluene diisocyanate (TDI) and 4,4′-methylenediphenyl diisocyanate (MDI). Special grades with good lightfastness contain *m*-tetramethylxylene diisocyanate (TMXDI) [511] or dicyclohexylmethane 4,4′diisocyanate (HMDI, also H12MDI, SMDI, DCHM) [512], [513]. Where a special function is required that enables cross-linking with sulfur, OH-functional compounds with a double bond are used, such as glycerol monoallyl ether or trimethylolpropane monoallyl ether [497], [502].

Producers and Markets. In 2002 the estimated world market (not including the CIS and the Peoples' Republic of China) was ca. 1500 t/a. Suppliers of millable polyurethanes are:

Bayer/ Rheinchemie	Urepan
SBU	Sumipan
TSE Industries	Millathane
Uniroyal	Adiprene, Vibrathane

5.3. Thiokol Rubber

5.3.1. *Properties, Grades, and Applications*

5.3.1.1. *History*

Credited as being the oldest synthetic rubber still in production, thiokol rubbers [63148-67-4] (international abbreviation T) have changed considerably in character since their discovery in the 1920s [514-518]. This family of products was the result of attempts to utilize refinery fractions to produce glycols by chlorinating the olefins contained in these fractions and reacting the products obtained with alkali. The lack of success led PATRICK and MNOOKIN [516], [517] to react the chlorinated products with sodium di- and polysulfides, a polycondensation reaction that is still the basic approach to the production of thiokols.

The initial *type A polymer* was prepared from 1,2-dichloroethane [107-06-2] and sodium polysulfide, to yield a polymer with an average of four sulfur atoms between the alkyl groups in the polymer chain. After initial development by Thiokol Corporation, United States, in 1929, these polymers were prepared in

several countries. Type A polymers all suffer from two disadvantages: the physical properties of their vulcanizates are poor compared to those of natural rubber, and an unpleasant odor is given off during their difficult processing even after they are cured.

In 1934, *type B* tetrasulfide polymers were prepared by using a dichlorinated ether monomer. Later developments included homopolymer disulfide ethers *type D* and copolymers of disulfide ethers and ethylene dichloride (*types EB* and *F*). Today only FA and ST rubbers, a range of liquid rubbers, and the water dispersions MX and WD-6 are on the market.

5.3.1.2. *Grades*

The monomer compositions of the polysulfide rubbers now available are given in Table 36. The use of bis(2-chloroethoxy)methane [111-91-1] — often referred to as "formal" — improved the processibility of polysulfide elastomers, reduced their odor, and improved their low-temperature properties. At the same time the fuel and oil resistance of the formal-based products, although by many standards excellent, is not as good as that of the original polysulfide elastomers.

Table 36. Monomer composition of presently available polysulfide rubbers *

Type	Sulfur content, %	$C_2H_4Cl_2$	Formal	1,2,3-Trichloropropane
FA	47	x	x	
ST	37		x	x
LP	varying		x	x

* x = incorporated in the molecule.

The *FA materials* have terminal hydroxyl groups, although due to their very high molar mass (see Table 37) this generally does not influence curing or properties. The typical properties of FA and ST rubbers are given in Table 37.

Table 37. Typical properties of FA and ST raw rubbers

	FA	ST
Physical form	millable rubber	
Color	light brown	
d (at 23 °C)	1.34	1.27
Mooney viscosity ML1+4		
100 °C		30 – 40
123 °C	60 – 110	
Molar mass, g/mol	200 000	80 000
Odor	slight polysulfide	
Bin stability	limited	

Both *ST and LP grades* have terminal SH groups. The grades of LP rubber available are given in Table 38 together with their typical molar masses and viscosities LP-33 has a content of SH groups of 5.24 % [552].

Table 38. Properties of different grades of LP rubber

Polymer	mol % cross-link	Molar mass, kg/mol	Viscosity, Pa · s
LP 2	2.0	1000	130
LP-12	0.1	4000	4 000
LP-31	0.5	7000	11 000

Polysulfide water dispersions typically contain 50 % (MX grades) and 75 % (WD grades) polymer, stabilized against coagulation by $Mg(OH)_2$ and an added wetting agent. The dispersed rubber has an average particle size of ca. 10 µm.

5.3.1.3. *Mechanical Properties, Cross-Linking, and Applications*

Mechanical Properties. FA and ST polysulfide rubber compounds are flexible down to ca. – 45 °C (FA) or – 51 °C (ST), even over long periods of time in the presence of oils or solvents. Therefore, addition of a plasticizer is not required. The glass transition temperature of poly(ethyl formal disulfide) is ca. – 59 °C [519]. The even better resistance of FA rubbers against swelling in hydrocarbon oils can be attributed to their greater sulfur content. In ASTM no. 3 fluid a typical ST formulation exhibits a volume swell of about 18 % after 7 d [520]. Both types have modest heat resistance up to ca. 70 °C, and the thiol-terminated (i.e., ST) types can be used up to 125 °C where compression set is not critical [520]. A major difference between FA and ST rubbers is their resistance to compression set; FA types yield compounds with poorer compression set. Typical formulations and properties of FA and ST rubbers are shown in Tables 39 and 40.

Table 39. Typical formulations of FA and ST

Composition	FA	ST
Rubber, phr	100	100
N774 Black, phr	60	60
Stearic acid, phr	0.5	1.0
Zinc oxide, phr	10	5.0
Calcium oxide, phr		1.0
MBTS *, phr	0.3	
DPG **, phr	0.1	

* MBTS = dibenzothiazyl disulfide.
** DPG = *N,N′*-diphenylguanidine.

Table 40. Typical properties of FA * and ST ** compounds

Property	FA	ST

Hardness Shore A (23 °C)	70	67
Compression set, % (22 h, 70 °C)	20	15

* Cure 40 min at 150 °C.
** Cure 30 min at 155 °C.

Improvements in processing and increased ability to fill FA grades can be achieved by masticating them with, for example, benzothiazyl disulfide or thiuram disulfide in the presence of catalysts such as diphenylguanidine. As an example, addition of ca. 0.3 parts thiazole and 0.1 parts guanidine is quite efficient. An alternative is to blend the thiokol rubber with up to ca. 20 wt % of other polymers such as CR or NBR. The second polymer is chosen according to the solvent resistance required; thus, if resistance to ketones is required, CR should be employed, whereas a better resistance to aromatic or halogenated solvents is achieved with NBR blends [530].

Cross-Linking and Compounding [532, 533, 538]. *Hydroxyl-terminated* types are, after mastication, generally cross-linked by using zinc oxide [521]. For *thiol-terminated* polymers, many cross-linking reactions are possible, but generally zinc peroxide is used for the solid rubber, and lead or magnesium oxide or calcium peroxide is used for the liquid rubber. Although organic peroxides can be used, those that yield acidic byproducts should be avoided, since these can lead to polymer degradation.

Carbon black and *mineral fillers* are added to thiokol compounds and have similar effects as in other rubber systems. However, due to the intractability of the batch, only up to 100 parts of filler are added to the liquid systems. Acidic fillers should, however, be avoided because these too can lead to polymer degradation.

Plasticizers are rarely used because the low-temperature properties of these rubbers are adequate without them. However, plasticizers such as butyl benzyl phthalate are added to liquid thiokols if very soft compounds (down to 20 Shore A) are required. Alternatively the cure reaction can be limited by adding monofunctional mercaptans, such as cetostearyl mercaptan (e.g., 1.5 parts) [522].

Applications. Thiokol rubbers find use where their service temperature range of ca. – 45 to 100 °C (intermittently up to 150 °C) and their excellent resistance against oil and chemicals give them advantages over other elastomers [529]. Thiokols are widely used as sealants for heavy construction, building, or automotive application [528, 547-550, 551-543, 544]. The material is especially used as a sealant material for insulating glass to prevent condensation [534], [531, 535-537, 546]. Other applications are as modifiers for epoxy resins, as adhesives, or printing rolls and blankets [527, 553-555]. The liquid systems find particular use in fabric coatings and as coating materials generally [540, 545, 556].

Although the water dispersions of thiokol rubbers do not, alone, form continuous films on drying, the addition of a “softener” (such as ammonium hydrosulfide, tetramethylthiuram disulfide, benzothiazyl disulfide, or piperidinium pentamethylene dithiocarbamate) leads to chain scission and a transient softening, which allows a continuous film to form. These water dispersions are used extensively as concrete liners and, more generally, for films and fabric coatings having the flexibility and solvent resistance typical of polysulfide rubbers.

5.3.2. *Basic Chemistry and Production Processes [519], [523]*

Thiokols are polycondensates from bis(2-chloroethoxy)methane and sodium polysulfide. The general reaction is:

$$n\,\mathrm{ClRCl} + n\mathrm{Na_2S_x} \rightarrow \left(\mathrm{R-S_x}\right)_n + 2n\,\mathrm{NaCl}$$

where R = $^{\bullet}CH_2CH_2OCH_2OCH_2CH_2{}^{\bullet}$

so that, after isolation, the polymer has the general formula:

$$\mathrm{HO(CH_2CH_2S_xCH_2CH_2OCH_2OCH_2CH_2S_x)_nCH_2CH_2OH}$$

Depending on the thiokol type, either 1,2-dichloroethane or 1,2,3-trichloropropane [96-18-4] is employed as comonomer. The reaction is carried out in an aqueous dispersion in the presence of magnesium hydroxide. Formally, the latter acts as a nucleating agent for the polymer when it is precipitated by adjustment of the pH of the reaction mixture to ca. 5 – 6. The FA type polymer is isolated without further reaction steps, washed to remove inorganic salts and low molar mass material, and finally dried. The last stage involves exposure to air, which completes chain termination. The resulting hydroxyl-terminated polymer has a molar mass of ca. 200 000 g/mol and a very narrow molar mass distribution.

Before isolation of *thiol-terminated polymers* which are polymerized using 1,2,3-trichloropropane as a branching/cross-linking agent, sodium sulfite and sodium sulfhydrate (an aqueous solution of sodium hydrosulfite) are added to the reaction mixture. The former ensures that the number of sulfur atoms between the $CH_2CH_2OCH_2OCH_2CH_2$ groups is reduced to two. The sulfhydrate reacts with disulfide groups to cleave the polymer chain and introduce the thiol end groups. Polymer isolation is similar to that for hydroxyl-terminated polymers.

5.3.3. *Producers and Production Capacities*

The world production capacity for polysulfide rubbers was presumably some 40 000 t/a in 1999 [524]. The major producer of thiokol rubbers is Morton Thiokol, United States, whose capacity is estimated to lie between 9000 and 30 000 t/a [558], [524]. Toray Thiokol (estimated 2000 t in 2000) [525] in Japan, a joint venture between Morton and Toray, and Chemiewerk Greiz-Dolau in Thüringen, Germany — which was taken over by Harrisons & Crosfield (Manchester) in 1992 [539] — also make similar products. The latter has a probable capacity of some 5000 t/a [526].

6.1. Halobutyl Rubber

6.1.1. *Introduction*

The halobutyl rubbers, bromobutyl (BIIR) and chlorobutyl (CIIR) rubbers were first investigated by R. F. MORRISSEY of B. F. Goodrich in the mid-1950s [559-562]. MORRISSEY showed that halogenating the isoprene groups in IIR produced a rubber which could co-cure (vulcanize) with elastomers such as NR, BR, and SBR while preserving the essential properties of IIR. Goodrich marketed a brominated butyl rubber (Hycar 2202) produced by mill-mixing IIR with *N-bromosuccinimide* from 1954 – 1969. Independently, Michelin developed a similar brominated polymer [563] that was used internally in tubeless

radial tires.

Exxon developed the commercial chlorination of IIR with *elemental chlorine*. It showed that the chlorination was a substitution reaction and that HCl was released [564-566]. Polymer degradation, which occurred in chlorination, was overcome by limiting the amount of chlorine used to less than 1 mol per mole of isoprene in the IIR. In the early 1960s, Exxon introduced several grades of CIIR that differed mainly in molar mass.

Bromination of IIR with *elemental bromine* was developed and a commercial product introduced by Polysar in the late 1960s and early 1970s. Both types of bromination are substitution reactions, analogous to chlorination.

Halobutyl rubbers are more easily vulcanized than IIRs because the allylic halide groups make them more reactive.

6.1.2. *Properties, Grades, and Applications*

Properties. BIIR contains approximately 1.8-2.1 wt % bromine, and CIIR contains 1.2 wt % chlorine. Other than the density of BIIR, which is 930 kg/m^3, the physical properties of BIIR and CIIR are similar to those of IIR (see Section Properties, Grades, and Applications).

At temperatures above 150 °C, BIIR under-goes dehydrobromination, cross-linking, isomerization, and chain scission reactions, the latter two reactions being accelerated in the presence of acids. Dehydrobromination of the endo and exo structures (see Section Basic Chemistry) forms conjugated diene units each of which can appear as two isomeric configurations. BIIR is stabilized by calcium stearate and epoxidized soybean oil (ESBO), which react with any released HBr. CIIR is more stable than BIIR, and therefore lower amount of calcium stearate is added as stabilizer. Calcium stearate is also a cure retarder.

For example, when a solution of CIIR is heated with calcium oxide in the presence of a small amount of a zinc carboxylate (usually stearate), the polymer is dehydrochlorinated to give a butyl rubber containing conjugated diene groups [595], which can be cured with peroxides and reacted with styrene and maleic anhydride resins to give interpenetrating networks [585]. BIIR, under the same conditions, rearranges and cross-links to the bromomethyl structure [572].

Both BIIR and CIIR cure when heated with zinc oxide in the presence of stearic acid [559]. For BIIR, a higher fraction of the limited olefinic functionality is converted to cross-links than for CIIR, and the effect is more pronounced for the rearranged form of BIIR [572], [586]. Conventional sulfur curatives achieve a rapid, effective cure, even in the presence of highly unsaturated polymers such as NR, BR, and SBR, which prevent IIR from curing [559]. The faculty of the halobutyl rubbers for curing in the presence of other elastomers has led to their widespread use in tire inner liners.

The halobutyl rubbers cross-link with resins, various amines [586], dienophiles [587], and other curatives [588]. The curing reaction is usually faster than that of IIR, and the vulcanizates are usually formulated to be more resistant to heat. Because of this cure versatility, halobutyl rubbers have displaced IIR in applications such as pharmaceutical closures, tank linings, and mechanical goods.

Applications. During the 1960s the quantity of CIIR used for previous IIR applications increased as CIIR was adopted for the inner liners of tubeless tires. In this application, CIIR is usually blended with NR in ratios of ca. 70 : 30. Since BIIR is more reactive than CIIR it co-cures more effectively with highly unsaturated elastomers. BIIR is the elastomer of choice for inner liners containing no NR, such as for truck tires.

Halobutyl rubbers continue to replace IIR with tubeless tires replacing tubed tires. An estimate of the amounts of IIR and halobutyl rubber used in various applications is given in Section Properties, Grades, and Applications.

Grades. BIIR and CIIR are produced by Bayer and Exxon. Grades differ in Mooney viscosity and, hence, processibility of the polymers. Grades from each producer are listed in Table 41 with typical values of the parameters used for specification purposes. As with IIR, specification ranges differ slightly according to source.

Table 41. Grades and typical properties of halobutyl rubber

Producer and properties	Bromobutyl grades			Chlorobutyl grades

6.1.3. *Basic Chemistry and Production Process*

6.1.3.1. *Basic Chemistry*

According to the generally accepted [564, 569, 573-575] mechanism halogenation of butyl rubber proceeds through the formation of a halonium ion. It was also suggested that in the initial stage, a molecular complex forms between the halogen and the C ═C double bond [574], [576]. The presence of the sterically bulky methyl group in the β position prevents the attack of the halide ion at the tertiary carbon atom and therefore the formation of an addition product [569]. As a result, the energetically less favorable process of elimination of hydrogen halide, leading to substitution products, becomes the predominant pathway [569]. Recently it was proposed that the byproduct HCl accelerates chlorination of natural rubber [574] as well as butyl rubber [575] and excess of bromine acts as a catalyst in the bromination of bromobutyl rubber in a nonpolar reaction medium [577].

The main product is a secondary allylic halide structure where the double bond is external relative to the backbone of the polymer. This structure is referred to as “exomethylene” or “exo”. The minor product is another secondary allylic halide in which case the double bond is located in the backbone. This structure is referred to as “endo”. The byproduct of the main reaction, hydrogen halide, can also react with the double bond. The secondary allylic “exo” structure can rearrange to a thermodynamically more stable primary allylic form in the presence of acids, such as the byproduct HX [573], [578]. Dehydrobromination of the already formed allylic structures can also occur leading to the formation of conjugated diene structures. These primary and secondary structures are shown in Figure 22. In [570-572], the structures originally suggested in [573] are designated as shown in Figure 22.

Figure 22. Principal structures present in halobutyl rubber

Commercial BIIR base polymer contains about 1.7 – 1.9 mol % of isoprene monomer, of which 0.5 – 0.6 mol % is not brominated. Of the approximately 1.0 mol % brominated, about 0.9 mol % is converted to the exomethylene form and the remainder to the endo and rearranged structures, with a trace of the endo-conjugated form. CIIR base polymer typically contains 2.1 – 2.3 mol % of isoprene, of which 1.7 – 1.8 mol % is chlorinated. Approximately 1.3 – 1.4 mol % is converted to the exo form and 0.4 – 0.5 mol % to *cis* and *trans* endo isomers. The rearranged form does not occur in CIIR.

6.1.3.2. *Production*

Chemicals Used in Production. The principal chemicals employed in the production of halobutyl rubber from IIR are the elemental halogens, hexane as solvent, sodium hydroxide as neutralizing agent along with calcium stearate and ESBO, which are used to control stability and cure behavior [567].

Solvent Process. Halobutyl rubber is produced by contacting a solution of regular butyl base polymer in an alkane (the solution is known as cement) with halogen in an agitated vessel. Unreacted halogen and hydrogen halide formed as byproduct are extracted from the cement, and additives are incorporated. The solution is steam-stripped to remove the solvent, giving a solid product. The solid material is finished by methods similar to those described in Section Industrial Production for regular butyl rubber. A process flow sheet is shown in Figure 23.

Figure 23. Flow diagram for production of halobutyl rubber

a) Cement storage; b) Halogenator; c) Aging drum; d) Neutralizer; e) Hexane receiver; f) Coagulator; g) Stripper; h) Finishing extruders

Dissolution of Rubber. The halogenation operation begins with a solution of rubber in an alkane, usually hexane. The rubber is dissolved either directly by the solvent replacement process (see Section Producers and Production Capacities), or indirectly by dissolving solid rubber produced by the slurry process (see Section Producers and Production Capacities) [581].

Solutions of butyl rubber are prepared by dissolving rubber crumb directly from the vacuum strippers (see Fig. 16), or from chopped or ground bales of rubber from a conventional finishing process. The time for complete dissolution depends on temperature, particle size, agitation, and molar mass; 1 – 4 h are normally required.

Chlorination and Bromination. Chlorination and bromination are conducted in one or more intensely agitated vessels.

The *chlorination reaction* is carried out by contacting the rubber cement with a solution of chlorine or with chlorine vapor at 25 – 65 °C. Chlorine reacts violently with many hydrocarbons, including butyl rubber solutions, so its concentration must be kept low. As discussed above, the reaction consists of replacement and rearrangement, producing hydrogen chloride as byproduct. The quantity of chlorine added is essentially stoichiometric.

Addition of bromine to the polymer proceeds more slowly than that of chlorine, so the cement can be contacted directly with liquid bromine. Reaction temperatures are comparable to those for chlorination. To provide more time for reaction at low temperature, the reaction mixture passes through a residence time vessel after the mixer. More than a stoichiometric amount of bromine must be used to obtain a sufficient reaction rate without product breakdown. As in CIIR manufacture, hydrogen bromide is a byproduct.

Neutralization. The hydrogen bromide and unreacted bromine are neutralized promptly to avoid undesirable side reactions that reduce product stability. Hydrogen chloride is also neutralized while chlorine reacts to completion. Neutralization is conducted by dispersing the halogenated cement in a sodium hydroxide solution with high-intensity mixers.

Product Recovery. The product is recovered as a 5 – 12 % slurry in water by contacting it with steam and water in a process similar to that described in Section Ethylene – Propene Elastomers (EPM, EPDM) for regular butyl rubbers. The stabilizers calcium stearate and ESBO, as well as an antioxidant, are added to the rubber immediately before recovery.

The rubber is finished with mechanical drying equipment in a process similar to that used for regular butyl rubber (see Section Ethylene – Propene Elastomers (EPM, EPDM)). Because of the greater reactivity of the halogenated product, less severe conditions are employed.

Extruder Halogenation. Butyl rubber has been halogenated in the solid phase in an extruder-based reactor in which the bulk phase is in direct contact with chlorine or bromine [589]. Because the operation is substantially free of water, the hydrohalic acids formed as byproducts do not dissociate and are removed by an extruder devolatilization, thereby avoiding the need for dispersed-phase neutralization.

6.1.4. *Chemical Analysis*

The *IR spectra* of BIIR and CIIR are very similar to those of IIR, except for peaks at 910 and 1637 cm^{-1} due to the $=CH_2$ group [590]. The absorption at 910 cm^{-1} is a shoulder, and the peak at 1637 cm^{-1} is small and broad; however, they can be used to determine the amount of exomethylene structure present in the rubber.

The *proton NMR spectra* of BIIR and CIIR are very similar [591]. Figure 26 shows the 500 MHz ^{1}HNMR spectra of a typical bromobutyl sample with the assignment of the resonances present in the olefinic region.

Figure 26. Schematic for HNBR production

a) Solution production; b) Hydrogenation (homogeneous or heterogeneous); c) Catalyst separation; d) Isolation of HNBR

6.1.5. *Storage and Transportation*

The halobutyl rubbers are packaged, shipped, and stored in the same manner as IIR (see Section Producers and Production Capacities). Shelf life is about 60 months if the polymer is not subjected to high temperature during storage.

6.1.6. *Legal Aspects*

BIIR and CIIR comply with U.S. FDA 21 CFR 177.1210 (sealing gaskets for food containers) and are allowed in articles intended for repeated use (CFR 177.2600). Local regulations are applicable.

6.1.7. *Producers and Production Capacities*

BIIR and CIIR are produced by Exxon and Bayer in plants that either are used only for production of halobutyl rubber or can produce both halobutyl and IIR. Estimated production capacities of IIR and halobutyl rubber are given in the section on IIR (Table 25)

Table 25. Uses of IIR and halobutyl rubber by region in 10^3 t/a

	IIR			Halobutyl rubber		
Use	**America**	**Western Europe**	**Asia**	**America**	**Western Europe**	**Asia**

.

6.1.8. *Toxicology and Occupational Health*

Halobutyl rubbers are regarded as nonhazardous and can be processed like other elastomers. Traces of halogenated hydrocarbons are present in both BIIR and CIIR. The levels are too low to be hazardous [593], but must be considered where extraction may lead to unfavorable consequences.

The presence of halogenated polymers must be considered if used tires are incinerated.

6.1.9. *New Commercial Development*

Star-Branched Halobutyl Rubber. Chlorinated or brominated versions of star branched butyl rubber (see Section Industrial Production) are made in an analogous manner to CIIR and BIIR [594].

Brominated Isobutene/p-Methylstyrene Copolymer. Conventional halobutyls are based on the copolymer of isobutene and isoprene. In the early 1990s Exxon developed a new type of bromobutyl rubber, which is made by the free radical bromination of isobutene/*p*-methylstyrene copolymers and commercialized under the EXXPRO trade name. The isobutene/*p*-methylstyrene copolymer is made by conventional cationic polymerization using $AlCl_3$ or alkyl aluminum coinitiator at low temperatures in methyl chloride diluent [581], [579] as it is in the case of IIR. The *p*-methylstyrene content of these polymers is between 2.5 – 7 mol % the rest being isobutene [580]. By the free radical bromination, 0.5 – 1.2 mol % of the incorporated *p*-methylstyrene units are converted to benzylic bromide structure. The fully saturated backbone of this polymer results in an improved ozone resistance compared to conventional halobutyl elastomers.

6.2. Chloropolyethylene and Chlorosulfonyl Polyethylene

Because of its high chain mobility, polyethylene has a very low glass transition temperature. However, because of the regular chain structure it also crystallizes very readily, so that it is a thermoplastic below its melting point. Functional groups, which hinder crystallization, can be introduced by polymer modification reactions. This, however, decreases chain mobility because of steric hindrance, and the glass transition temperature is raised. Within certain limits of chlorine contents, polymers with rubbery properties are obtained. The chlorination (CM) and chlorosulfonation (CSM) of polyethylene are important industrially.

6.2.1. *Chloropolyethylene*

6.2.1.1. *Properties, Grades, and Applications*

The properties of CM are determined principally by the chlorine content [582], [583].

Polymers with chlorine content of < 20 wt % show a noticeable degree of crystallinity because of the presence of polyethylene sequences. At > 50 wt % chlorine the strong interactions of the C – Cl dipoles result in hard, brittle, but noncrystalline products. Polymers with between 25 and 40 wt % chlorine are suitable for rubber applications. At a chlorine content of ca. 35 wt % the crystallinity of the chain disappears completely. These polymers possess the best low-temperature flexibility (brittleness point ≤ – 40 °C) and the lowest softening point (≤ 20 °C). The effect of using different types of polyethylene is observable only at a chlorine content of < 30 wt % [584]. Thus, if the more crystalline and less branched high-density polyethylene (HDPE) is chlorinated to a chlorine content of 15 wt % it exhibits the same degree of crystallinity as unchlorinated low-density polyethylene (LDPE).

The CM grades are available commercially in powder form, and differ in chlorine content and viscosity. Their vulcanizates are characterized by very high

resistance to hot air, oil, and chemicals and by very high flame resistance. At optimal composition they are very resistant to discoloration and ozone cracking. In the range of 36 – 44 wt % chlorine, which is typical for most of the CM grades, oil resistance, tear strength, flame resistance, and gas impermeability improve with increasing chlorine content. However, plasticizer sorption, compression set, and low-temperature flexibility deteriorate [596]. A comparison with vulcanizates of related rubbers is shown in Table 42. The relationships given depend on the composition.

Table 42. Comparison of CM vulcanizates with related rubbers [*][596]

CM can be compounded on conventional rubber-processing machines. Without addition of the common rubber chemicals, CM behaves more like a thermoplastic. It can be compounded particularly rapidly in a kneader by the upside-down method, in which the rubber powder is added last. A thermal softening effect during processing is typical for CM. Like every chlorine-containing polymer, CM must be stabilized against loss of HCl at high processing or application temperature [597]. Metal oxides such as magnesium or lead oxide, basic lead salts, epoxidized soybean oil, and epoxy resins are suitable stabilizers, frequently in combination with one another. Zinc oxide and also other zinc compounds must not be used as stabilizers because they drastically reduce the resistance to aging of the vulcanizate. Because of the absence of double bonds, lower degree of branching (tertiary chlorine), and random incorporation of chlorine atoms in the polymer chain, CM elastomers are thermally more stable than PVC or CR. However, CM cannot be vulcanized with sulfur. Organic peroxides are most frequently used for *vulcanization*, usually in combination with multifunctional vinyl or allyl compounds (e.g., triallyl cyanurate). Cross-linking can also be carried out by using energy-rich radiation or — for articles that do not require high thermal stability — via a thiadiazole – amine system. CM is used mainly in the cable and wire sectors for the production of oil- and flame-resistant sheathing. Other uses include technical rubber goods such as hose (particularly hydraulic and chemical hose), collars, dust caps, and seals in car and plant construction [596].

6.2.1.2. *Basic Chemistry and Production Processes*

The first chloropolyethylenes were produced by chlorination of LDPE in solution (e.g., in CCl_4). This resulted in a random distribution of chlorine atoms along the polymer chain. Currently, HDPE is used as starting material and is chlorinated mainly in aqueous suspension. Polyethylene must be in powder form to provide a large surface area for chlorination. The reaction is performed in several stages to achieve optimal chlorination and avoid agglomeration of the powder particles [598-601]. In the first stage the reaction is carried out below the melting point of polyethylene which leads mainly to chlorination at the amorphous phases. The product is then heated above the melting point of the crystalline phases, and chlorination is continued. Occasionally, chlorination is completed in a third stage at a lower temperature. The CM powder is washed free of HCl, water is removed by centrifugation, and the product is dried and packed in sacks.

6.2.2. ***Chlorosulfonyl Polyethylene***

6.2.2.1. *Properties, Grades, and Applications*

Chlorosulfonyl polyethylene (CSM) contains, besides chlorine atoms, small quantities of sulfonyl chloride groups distributed randomly along the polymer chain.

Commercial CSM grades contain between 25 and 43 wt % chlorine and 0.8 – 1.5 wt % sulfur, and have Mooney viscosities between 20 and 110 [602], [603]. In a product containing, for example, 25 wt % chlorine and 1.0 wt % sulfur, ca. every 80th carbon atom carries a sulfonyl chloride group, and every 7th or 8th carbon atom is chlorinated. In many properties, CSM is similar to CM because of the comparable chlorine content. However, the chlorine atoms of sulfonyl chloride groups are significantly more reactive than those bonded to carbon atoms and can undergo cross-linking reactions [603]. The vulcanization of CSM can take place

1. In the presence of moisture and a divalent metal oxide (e.g., MgO or PbO) with the formation of ionic cross-linking bridges. This reaction is slow and is particularly suitable for vulcanizates used in roofing and for linings for reservoirs and basins.
2. With MgO and sulfur-containing accelerators, such as mercaptobenzthiazole or thiuram disulfides. If the vulcanizates are to be used at elevated temperature (up to 150 °C), polyfunctional alcohols (e.g., pentaerythritol) are added. These applications include hydraulic tubes and cable covering.
3. With peroxides, by irradiation, or together with epoxy resins.

In addition CSM is used for fabric coatings, roller coatings, extruded good, seals, and molded articles.

A new development is the production of so-called *alkylated chlorosulfonated polyethylene* (ACSM) [604-606]. Alkylated chlorosulfonated polyethylene has short alkyl side groups on the polymer chain, which replace some of the chlorine atoms (chlorine content: 26 – 30 wt %) and act as internal plasticizers.

The products have glass transition temperatures about 5 °C lower than CSM, better heat resistance, and lower oil resistance. Unlike standard CSM, ACSM is also suitable for dynamic stressed parts, such as timing belts, axle boots, and poly-V-belts.

6.2.2.2. *Basic Chemistry and Production Processes*

Chlorosulfonyl polyethylene is produced commercially by simultaneous chlorination and chlorosulfonation of *LDPE* or *HDPE* in an inert solvent (e.g., CCl_4) with a mixture of gaseous chlorine and sulfur dioxide under UV irradiation [607]. The product is processed by application of a concentrated solution of the

product to two drying rollers placed close together, which are heated to 100 – 200 °C. The rubber layer is stripped off the rollers with a knife [608]. Spray drying or pouring the polymer solution into hot water above the boiling point of the solvent, with the addition of $MgCO_3$, for example, to avoid lump formation, is also described [609]. CSM can also be produced by chlorosulfonation of *CM powder* with gaseous chlorine and sulfur dioxide in a fluidized-bed reactor at 20 – 100 °C under UV [610]. *Linear low-density polyethylene* (copolymer of ethylene and short-chain α-olefins) is most likely used as the starting material for ACSM.

6.2.3. *Producers and Production Capacities*

In 1991 the worldwide capacity for CSM was 56 600 t, and for CM 51 400 t [611]. The largest proportion of CM is used not in the elastomer sector, but for modifying thermoplastics, mainly PVC. The producers, trade names, production sites, and capacities for CSM and CM are listed in Table 43.

Table 43. CSM and CM producers and production capacities

Producer	Type	Trade name	Production site	Production capacity, t/a
Denki KK	CSM	Denka-CSM	Omi/Japan	2 000
Du Pont	CSM	Hypalon	Beaumont/United States	34 500
Du Pont	CSM	Hypalon	Londonderry/Northern Ireland	18 100

Showa Denko	CM	Elaslen		3 000
Du Pont	CM	CP-R		

* Estimated, no information from the producer.
** Production expansion to 12 000 t/a planned.

6.3. Hydrogenated Nitrile Rubber

6.3.1. *Properties, Grades, and Applications*

Introduction. The selective hydrogenation of the C – C double bonds in NBR leads to a specialty rubber, hydrogenated nitrile rubber (HNBR), which can be processed into vulcanizates with a balanced property profile [612-625]. The vulcanizates are characterized by

1. Excellent mechanical properties
2. Very good abrasion resistance
3. Very good resistance toward industrial oils
4. Very good low-temperature impact and flexural resistance
5. Very good ozone and hot-air resistance
6. Good resistance to alkali
7. Low steam and gas permeability

The reaction scheme of NBR hydrogenation and the chemical formula of HNBR [88254-10-8] are given below:

Grades. Completely and partially hydrogenated HNBR grades with acrylonitrile contents between 34 and 49 wt % and Mooney viscosities between 50 and 152 [ML 1+4 (100 °C)] are on the market.

Completely hydrogenated grades are defined here as those in which the degree of hydrogenation is 99 %. *Partially hydrogenated grades* have a degree of hydrogenation < 99 %; those with a degree of hydrogenation between ca. 90 and 98 % are of particular technological interest because they can be vulcanized using traditional sulfur systems.

Raw Rubber. Investigations of the *microstructure* of HNBR with different degrees of hydrogenation using pyrolysis – GC, IR and NMR spectroscopy have been described [626]. The degradation of HNBR under different conditions and various influences has also been investigated [627], [628].

The density of HNBR depends on the acrylonitrile content. For instance, HNBR containing ca. 43 wt % has a density of ca. 0.97 g/cm^3; whereas that containing ca. 34 wt % acrylonitrile, has a density of 0.95 g/cm^3.

Completely and partially hydrogenated NBR exhibits spontaneous and elongation crystallization [629], [630]. The variation of the glass transition temperature of NBR with its acrylonitrile content obeys the Gordon – Taylor relationship for random copolymers. In contrast, completely hydrogenated NBR and ethylene – acrylonitrile copolymers with acrylonitrile content < 55 wt % do not obey this relationship (see Fig. 24). The T_g (mechanical – dynamic measurement at 11 Hz) of products with an acrylonitrile content of 18.9 – 39.0 wt % is between –25 and –21.5 °C. At a content of 48.3 wt % acrylonitrile, T_g is –8 °C and thus markedly higher than expected from the Gordon – Taylor relationship [629]. A corresponding behavior is described for ethylene – vinyl acetate and ethylene – vinyl chloride copolymers of certain compositions, which has been attributed to crystallizing ethylene sequences.

Figure 24. Dependence of glass transition temperature on acrylonitrile content according to [629]

○ = Hydrogenated products; △ = Ethylene – acrylonitrile copolymers

The T_g of HNBR also depends on the degree of hydrogenation [616], [630], [631].

Products that exhibit significantly better low-temperature properties than conventional HNBR (TR 10 test according to ASTM D-1329 and T 10 test according to Gehmann) have been developed. They can be obtained by hydrogenation of ester-group-containing terpolymers based on NBR [632], [633].

Properties of the Vulcanizate. HNBR can be processed easily by the usual methods in the rubber industry. *Completely hydrogenated* NBR is vulcanized by using peroxides or high-energy radiation; *partially hydrogenated* NBR can also be vulcanized with sulfur and sulfur donors. Table 44 shows schematically the properties of vulcanizates derived from completely hydrogenated NBR, as a function of acrylonitrile content. Table 45 indicates the effects of the degree of hydrogenation and the nature of the cross-linking system on some vulcanizate properties.

Table 44. Effect of acrylonitrile content on the properties of HNBR vulcanizates (direction of the arrow indicates an increase in value or an improvement in properties)

Vulcanizates properties	Acrylonitrile content Low	High
Oil resistance	→	
Fuel resistance	→	
Tensile modulus	→	
Shore hardness	→	
Rebound resilience	←	
Gas permeability	←	
Heat buildup	←	

Table 45. Effect of degree of hydrogenation and cross-linking system on the properties of HNBR vulcanizates (direction of the arrow indicates an increase in value or an improvement in properties)

Vulcanizate properties	Completely hydrogenated grades	Partially hydrogenated grades
	Peroxide cross-linking	Sulfur cross-linking
Hot-air resistance	←	
Ozone resistance	←	
Tensile modulus	←	
Elongation at break	→	
Resistance to tear propagation	→	

HNBR can be compounded without a plasticizer in such a way that its vulcanizates have a *brittleness temperature* of <–70 °C according to DIN 53 546. The T_g of completely hydrogenated NBR can be lowered within certain limits by special compounding with plasticizers, without significant loss of heat resistance.

If magnesium and zinc oxides are replaced by zinc peroxide in the compounding of partially hydrogenated NBR, a vulcanizate with improved properties is obtained after cross-linking with sulfur donors in the presence of a small amount of sulfur (efficient vulcanization). These properties are tensile modulus, compression set, ozone and hot-air resistance, and dynamic load-bearing capacity [634]. However, to prevent accidents, only zinc peroxide made into a paste with plasticizer should be used.

Partially hydrogenated NBR that has been cross-linked with peroxides has a better low-temperature compression set than completely hydrogenated grades.

The heat resistance of vulcanizates from completely hydrogenated NBR is sufficient up to 150 °C — and that of NBR vulcanizates up to 120 °C — if residual elongation at break of 50 % after 1000 h aging is used as the criterion [612].

In Table 4 of Section Properties some properties of HNBR vulcanizates are compared with those of other rubber vulcanizates. The balanced property profile of HNBR can be clearly observed.

Applications. Because of its particular performance, HNBR can be used in the *automotive industry* for toothed and driving belts, and for various types of hosing and seals; in the *petroleum industry* for drill pipe protectors, pump stators, packing seals, and blowout preventors; in the *electrical industry* for cable coverings; and in the *machine construction industry* for laminating rollers.

The use of HNBR as a *modifier for thermoplastics* [635-644], as a *blend component for other rubbers* [645-656], and as a basic component for the production of *dynamically cross-linked thermoplastic elastomers* [657] has been claimed in various patent applications. EVM and FPM, for example, have achieved some importance as blend components for HNBR. *HNBR – EVM rubber blends* are suitable for cable coverings in ship construction. They meet the Naval Engineering Standard 518. *HNBR – FPM rubber blends* give vulcanizates with high fuel resistance and good mechanical properties. An *HNBR – PVC blend* has a better fuel resistance than HNBR [658].

6.3.2. *Basic Chemistry and Production Processes*

In the hydrogenation of NBR to HNBR the C – C double bonds must be able to be completely (selectively) hydrogenated if desired, without the triple bonds of the nitrile groups being attacked. Reduction of the nitrile groups leads to an increase in molar mass due to the formation of secondary and tertiary amines and eventually to insoluble products.

Determination of the degree of hydrogenation of HNBR can be carried out by IR and ^{1}H-NMR spectroscopy, and titrimetrically in chloroform by using the iodine number method according to ASTM D-1959 [659-661]. The acrylonitrile content can be determined, for example, by the Kjeldahl method or by elemental analysis according to Dumas.

In the current industrial hydrogenation processes, NBR solutions are reacted with hydrogen batchwise in a stirred vessel in the presence of homogeneous or heterogeneous catalysts. A schematic diagram for both processes is shown in Figure 25. The polymer concentration of the solution to be hydrogenated is ca. 15 wt %.

Figure 25. Schematic for HNBR production

a) Solution production; b) Hydrogenation (homogeneous or heterogeneous); c) Catalyst separation; d) Isolation of HNBR

Homogeneous Catalysis. In homogeneous hydrogenation, the catalyst, like the substrate to be hydrogenated, is dissolved in the solvent. Suitable catalysts are, for example, rhodium and ruthenium phosphine complexes [662-677]. With *rhodium catalysts* the process is carried out preferably in chlorinated aromatic hydrocarbons as solvent, in the presence of phosphine ligands if desired.

Depending on the type of *ruthenium catalyst* used, hydrogenation can be carried out in either the presence or the absence of free phosphines. Ketones, chlorobenzene, or mixtures of the two are used as solvent. The use of organometallic hydrogenation catalysts requires careful exclusion of oxygen.

Depending on the catalyst chosen and its concentration, the reaction temperature is usually between ca. 100 and 150 °C. The reaction pressure can vary from a few to ca. 190 bar.

The kinetics of selective hydrogenation of NBR with tris(triphenylphosphine)rhodium(I) chloride in chlorobenzene are known. The C – C double bonds of the 1,2-bonded butadiene units are hydrogenated most rapidly, followed by the 1,4-*cis*-bonded units, and the hydrogenation of 1,4-*trans*-bonded butadiene units is slowest [678], [679].

Heterogeneous Catalysis. In heterogeneous hydrogenation of NBR supported palladium catalysts in particular are used, which are dispersed in the dissolved substrate. The use of other supported noble-metal catalysts is also described. Carbon black, activated carbon, calcium carbonate, silicon dioxide, and titanium or zirconium dioxides can be used as catalyst support [680-685]. The reaction is usually performed in low molar mass ketone solvents. The preferred reaction temperature is ca. 50 °C and the reaction pressure ca. 50 bar. The hydrogenating activity of the catalyst can be improved by doping the palladium with other metals [680-685]. Particularly good hydrogenation results are obtained with silicon dioxide as the carrier material for the active metals if a specific surface area of 600 m^2/g is not exceeded and the average pore diameter is between 80 and 120 nm.

After hydrogenation the catalyst is usually removed from the reaction solution. Homogeneous catalysts can be removed by precipitation [686] or absorption [687], [688]; for heterogeneous catalysts, filtration or centrifugation are suitable [682]. The isolated catalysts are regenerated if necessary and then recycled into the hydrogenation process, or worked up.

HNBR is isolated by blowing steam through the solution, followed by drying or by direct evaporation of the solvent.

Besides the hydrogenation process described, other processes are known, for example,

1. Reaction of NBR with hydrogen in solution with palladium carboxylates [689]
2. Reaction of NBR with hydrogen in solution with a catalyst composed of a palladium and an organoaluminum compound [690]
3. Hydrogenation of olefinic double bonds in unsaturated polymers (including NBR) with hydrogen in solution with rhodium catalysts of the Wilkinson type, which are fixed on a polymer matrix [691]
4. Reaction of NBR latex with hydrogen in the presence of chlorobenzene by using tetrakis(triphenylphosphine)rhodium(I) hydride [665]
5. Hydrogenation of NBR latex with hydrazine as the hydrogen donor in the presence of an oxidizing agent and a metal-ion activator at atmospheric pressure [692]

6.3.3. *Producers and Production Capacities*

The worldwide production capacity of HNBR was ca. 4900 t in 1991. Of this, 1800 was attributed to Nippon Zeon (plant in Takaoka, Japan, trade name Zetpol) [693]; 1500 t to Zeon Chemicals, a subsidiary of Nippon Zeon (plant in Bayport, Texas, United States, trade name Zetpol); and 1600 t to Miles Inc., a 100 % subsidiary of Bayer AG (plant in Orange, Texas, United States, trade names Therban, Tornac) [694].

6.4. Polyphosphazenes (see also ⟶ Inorganic Polymers – Polyphosphazenes)

6.4.1. *Properties, Grades, and Applications*

Introduction. A rapidly growing branch of material science has been the area of inorganic and organometallic polymers. Polymers with main-chain building blocks containing atoms other than carbon offer a great variety in structure and often have greater bond energies than C – C single bonds with ca. 343 kJ/mol. An example is the P – N bond with 615 kJ/mol.

Polyphosphazenes, as one example of a polymer with an inorganic backbone, contain pentavalent phosphorus in a chain of alternating phosphorus and nitrogen atoms joined by alternating double and single bonds. All polyphosphazenes are grouped together under the abbreviation Z, with fluoroalkoxy elastomers being designated FZ and the aryloxyphosphazenes PZ.

The two organic moieties attached to each phosphorus atom can be varied to yield a very broad spectrum of materials with different properties; more than 300 different structures have been documented to date with new application under evaluation [695-719].

History. The ring-opening polymerization of hexachlorocyclotriphosphazene [940-71-6] [16422-79-0] dates back to 1897 and the work of STOKES. Without control, this reaction yields a cross-linked, rubbery material (also known as “inorganic rubber”), which quickly hydrolyzes [720-725].

Synthesis of the cyclic precursors from the reaction of phosphorus pentachloride and ammonia dates back to 1834 to the work of ROSE [726], and LIEBIG and WÖHLER [727]. This reaction usually leads to a mixture of cyclic trimers, tetramers, and linear oligomers with a degree of polymerization up to 20.

$$n + mPCl_5 + n + mNH_4Cl \rightarrow$$
$$\left(PCl_2=N\right)_n + \left(PCl_2-N\right)_m + 4\,HCl$$

n = 3,4; m = 5 – 20

In 1964, ALLCOCK et al. filed a patent for the preparation of a soluble poly(dichlorophosphazene) [26085-02-9] via a ring-opening polymerization of hexachlorocyclotriphosphazene and subsequent conversion of the resulting polymer to poly(organophosphazenes), which are suitable for technical applications [728-731].

6.4.1.1. *Properties*

The structural variety of polymers with a phosphazene backbone leads to a broad range of physical properties. The common feature of all phosphazene polymers is the inherent flexibility of the main chain and the high dipole moment resulting from the absence of any resonance between the alternating P – N single and double bonds [732-735]. For some polyphosphazenes, rotational barriers for the backbone as low as 420 kJ/mol have been measured. Such low values are in accordance with the low glass transition temperature of many polyphosphazenes [695-697], [736] (see Table 46). Unfortunately, the limited

thermal stability of the simple poly(alkoxyphosphazenes) restricts their technical application despite their low T_g [737], [738].

Table 46. Glass transition temperature (T_g), crystalline melting point (T_m), and decomposition temperature (T_d) for some polyphosphazenes

Substituent	T_g, °C	T_m, °C	T_d, °C	Reference
Cl	–63	30		[739]
OCH_3	–76			[729]
OCH_2CH_3	–84			[729]
OCH_2CF_3	–66	242	360	[729]
OCH_2CF_3, $OCH_2C_3F_7$	–77			[739]
OC_6H_5	–8	390	380	[729]
$NH(CH_3)$	14	140		[740]
$N(CH_3)_2$	–4			[731]
CH_3	–46			[741]

Poly(dichlorophosphazene) with a high molar mass is a transparent elastomer with excellent stress – relaxation behavior. Unfortunately, this polymer degrades on contact with moisture to yield ammonium chloride, ammonium phosphate, and HCl.

In contrast, *poly(organophosphazenes)* are relatively stable to hydrolysis and, depending on the nature of the substituents, behave as thermoplastics or as elastomers. With the exception of the elastomeric polyphosphazenes with C_1 and C_2 alkoxy side groups, most *alkoxy and aryloxy phosphazene homopolymers* are thermoplastics. In these polymers, microcrystallinity prevents the facile conformational changes necessary to impart elasticity. However, reducing the symmetry and regularity by introducing different substituents in a random manner can yield useful elastomeric materials such as the fluoroalkoxides or aryloxides [739-744]. Such “copolymers” also tend to exhibit better thermal stability [745], [746].

Crystalline polyphosphazenes often exhibit a first-order transition at a temperature T_1. Between T_1 and the melting temperature T_m, these polymers are in a mesomorphic or liquid crystalline state, which is neither nematic nor smectic in nature [747-752].

Some polyphosphazenes exhibit outstanding thermal stability as measured by thermogravimetric analysis (TGA), with initial weight losses occurring above 300 °C (Table 46). However, at these temperatures, depolymerization occurs with the formation of small cyclic phosphazenes, and the high decomposition temperatures measured may simply reflect the boiling points of the depolymerization products. Thus, gel permeation chromatography suggests that poly (trifluoroethoxyphosphazene) starts to depolymerize even below 200 °C [753-755]. Studies on the thermal degradation of poly(bis-trifluoroethoxyphosphazenes) and of random and block copolymers bearing trifluoroethoxy and alkoxyalkoxy groups indicate that the thermal stability of the copolymers decreases with increasing content of alkoxyalkoxy groups [756].

The fluoroalkoxy polyphosphazenes exhibit excellent stability toward aqueous acid and base as well as low volume swell in a variety of solvents [757]. Concentrated sulfuric acid does, however, lead to decomposition [730].

Nearly all polyphosphazenes have good flame-retardant properties with oxygen indices up to 70, low smoke emissions and low toxicity of combustion gases [740], [758-764].

6.4.1.2. *Commercial Grades and Applications*

Copolymers with trifluoroethoxide and telomer fluoroalkoxide side groups (trade name Eypel-F, Ethyl Corp., **1**) and with phenoxide and *p*-ethylphenoxide side groups (Eypel-A, Ethyl Corp., Orgaflex, Atochem, **2**) have been commercialized [765], [766].

1

2

Eypel-F is sold as compounds that can be used to manufacture goods having Shore A hardness from 40 to 90. The compounds are priced from about $ 200 to $ 600 per kilogram. Some typical mechanical properties of these compounds are shown in Table 47 [766].

Table 47. Physical properties of typical Eypel-F compounds

Property	Eypel-F		
	6504	7003	7001
Hardness Shore A	65	70	70
Modulus at 100 % elongation, MPa	4.1	9.0	6.7
Tensile strength, MPa	7.6	10.3	9.3
Elongation at break, %	200	120	140
Compression set (70 h at 149°C), %	50	20	30
Density, g/mL	1.74	1.85	1.77
Mooney viscosity (ML4), 100 °C	66	45	45
Crescent tear, die B, kN/m (ASTM D-624)	27	19.3	17.5

To allow a *sulfur or peroxide cure,* ca. 1 % of the side groups introduced carry an unsaturated bond such as, e.g., *o*-allylphenoxy groups. A radiation cure is also possible. Polyphosphazenes can be filled with silica, clay, carbon black, or a combination of these [745], [746]. With a T_g of ca. – 65 °C and a fluorine content of ca. 55 % the fluoroelastomers are suitable for use between – 60 and 175 °C. Their flame retardance is very good as is their fuel resistance. Some typical values of Eypel-F 7003 are given in Table 48 [766].

Table 48. Effects of fuel, lubricant, and hydraulic fluid on Eypel-F 7003

Medium *	Temperature, °C	Swell, vol., %	Tensile strength, %	Hardness, points
ASTM fuel C	100	19	–24	–12
Aviation 100	82	15	–28	–12
ASTM #3	150	2	–16	–2
MIL-H-5606B	135	4	–4	–3
MIL-H-83282A	135	2	–5	–3

* All samples were immersed for 166 h at the temperature given.

Typical *applications* for Eypel-F are as fluid-resistant diaphragms, seals, gaskets, O-rings, and vibration isolators. Although military applications were a major market in the past, they are becoming less important. Automotive and biomedical applications (such as dental liners) are now the main markets [767].

Fluoroelastomers (FKM) and fluorosilicone elastomers (MFQ) are high-performance elastomers with properties similar to polyphosphazenes. Compared to MFQ, commercial fluorophosphazene polymers (Eypel-F) exhibit superior resistance to tear and abrasion, and better flex fatigue.

The properties of FZ at high temperature (up to 140 °C) are comparable to MFQ. The continuous-use temperature for FZ is 175 °C (short term 200 °C), ca. 50 – 70 °C lower than that of FKM. Furthermore, FZ is less stable to hydrolysis than MFQ [755], [768]. The low-temperature flexibility of FZ (to – 65 °C) is comparable to that of MFQ and considerably lower than that of FKM (–18 °C) [768], [769]. At room temperature, FZ shows a greater tendency to swell in a variety of fluids than FKM; but at higher temperature, FZ performs better [743], [769-771]. Table 49 compares some properties of these elastomers.

Table 49. Comparison of some properties of FZ, MFQ, and FKM *

Property	FZ	MFQ	FKM
Abrasion and tear resistance	F	P	G
Heat aging at 140°C	E	E	E
Heat aging at 180 C	G	G	E
T_g, °C	–65	–68	–18
Resistance to			
Aliphatic hydrocarbons	E	E	E
Aromatic hydrocarbons	E	G	E
Alcohols	P	G	G
Aqueous solutions	F	G	G
Oxidation – ozone	E	E	E

* E = excellent, G = good, F = fair, P = poor.

Poly(aryloxyphosphazenes) are sold as foam tubing or foam sheeting with prices ranging from $ 75 – 270 per square meter for sheeting and from $ 33 – 49 per meter for tubing. Foam sheeting finds its major application as a halogen-free, flame-resistant noise insulator. Foam tubing is used mainly for pipe insulation, with military outlets forming the major market. Typical properties of Eypel-A foam are given in Table 50 [772].

Table 50. Typical properties for Eypel A foam

	Typical value
Flammability	
Limiting oxygen index (ASTM D-2863)	44 %
NBS smoke density (ASTM E-662)	
Flaming	70
Nonflaming	40
Surface flammability (ASTM E-162, flame spread index)	11
Acid Gas Generation (MIL-C-24640, 4.8.16)	0 mg HCl/g
Mechanical properties	
Density (ASTM D-1622)	72 kg/m^3
Compressive res. (ASTM D- 1056)	14 – 55 kPa
Tensile strength (ASTM D-412)	170 – 240 kPa
Compression set (ASTM D-1667)	25 %
Noise reduction coefficient (ASTM C-423)	0.3
Thermal conductivity (24°C, ASTM C-518)	0.037 W m^{-1} K^{-1}

6.4.2. *Basic Chemistry and Production Processes*

Both Elf Acquitaine (Atochem) and Ethyl Corp. have pilot plants to produce polyphosphazenes. Although no details have been disclosed by these companies, Ethyl Corp. operates under license from Firestone, whereas Elf Acquitaine apparently has its own technology.

Production of Poly(Dichlorophosphazene). A major stumbling block in the commercialization of polyphosphazenes is the high price of the “monomer” hexachlorocyclotriphosphazene. However, the patent literature documents a process that avoids isolation of the “monomer” [773-775]. In this process,

linear phosphazene oligomers [774] with an average degree of polymerization between 4 and 6 are prepared from phosphorus pentachloride and ammonium chloride in chlorobenzene. This reaction requires a long time at high temperature (e.g., 4 d at 130 °C). The solvent is then distilled, and the cyclic material is extracted with hexane. Ammonium chloride is added to the linear oligomers, and the temperature is increased first to 155 – 165 °C for several hours and then to 200 °C. During the process, ammonium chloride and chlorobenzene are added, while during the nitrogen sweep, cyclic oligomers are removed. Yields up to 60 % are claimed based on the phosphorus pentachloride used.

Elf Acquitaine probably prepares its chlorophosphazene polymers via an alternative method based, formally, on the polymerization of *N*-dichlorothiophosphoryl-*P*-trichloromonophosphazene or *N*-dichlorophosphoryl-*P*-trichloromonophosphazene, the latter being prepared from ammonium sulfate, phosphorus trichloride, and chlorine [776-782]. These are polycondensation reactions and are reported to give high yields of essentially linear poly (dichlorophosphazene).

The mechanism of polymerization, catalysis, and cross-linking reaction of the *cyclic trimer* in bulk and in solution has been summarized by HAGNAUER [783]. Additional development work to improve the efficiency of polymerization and minimize cross-linking has been carried out [784-787]. The simple polymerization of the cyclic trimer is very sensitive to traces of phosphorus pentachloride, which can act as a chain terminator, and also to water, which can act as an accelerator at low concentration but as an inhibitor at higher concentration [788-790]. A wide range of materials have been reported to catalyze polymerization of the cyclic trimer, a reaction that is thought to be a cationic addition polymerization [791].

Polymer Modification. By all these routes the polymer obtained must first be modified to replace all P-Cl groups in order to produce useful polymers. Industrially the introduction of fluoroalkoxy or aryloxy groups is probably carried out in either cyclohexane or a mixture of cyclohexane and C_5 – C_7 alkanes; the alkali-metal alkoxide is added as a solution in tetrahydrofuran [791].

The substitution reaction of linear poly(dichlorophosphazene) with alkali-metal alkoxides occurs readily and completely with sterically nondemanding substituents in refluxing benzene or tetrahydrofuran [788], [791-795]. However, if bulky substituents are introduced, the reaction may be incomplete, and more vigorous reaction conditions are required to achieve complete reaction within a reasonable time [742].

Substitution of the chlorine in poly(dichlorophosphazene) takes place with most nucleophiles, which can also react with the chlorine atoms of simple phosphorus compounds. Thus, a variety of side groups can be attached to the phosphazene backbone. However, organometallic reagents such as organomagnesium or organolithium reagents are exceptions and generally cause simultaneous degradation of the polymer, thus preventing access to the more thermally stable polyalkyl- and polyarylphosphazenes [795].

Two or more different alkoxy or aryloxy groups can be introduced by simultaneous reaction with mixtures of nucleophiles; this method is used commercially [745], [746]. Provided the nucleophiles are similar in shape and reactivity their distribution will be random [739], [742]. An alternative route is the metathetical exchange of ligands by treating an alkoxyphosphazene polymer with an alkali-metal salt of a second nucleophile [796].

Direct Routes to Polyphosphazenes. A direct route to a poly(trifluoroethoxyphosphazene) with moderate molar mass via the thermal polycondensation of tris(trifluoroethoxy)-*N*-trimethylsilylphosphoramine has been described by FLINDT and ROSE [797]. Subsequently, this synthetic route was developed by MATYJAZEWSKI et al., using various anionic initiators, such as alkoxides, fluoride ion, Lewis acids, or strongly nucleophilic amines. The reactions can be carried out at as low as 70 – 120 °C to yield high molar mass linear polymers [798], [799], [800].

A similar route, leading to poly(organophosphazenes) was introduced by NEILSON and WISIAN – NEILSON, based on the thermal polymerization of *N*-trimethylsilylphosphoranimines having trifluoroethoxy and trimethylsilyl leaving groups [698], [741], [801].

A development to broaden the range of properties is the introduction of other groups or atoms into the phosphazene backbone, allowing, e.g., ring-opening polymerization at lower temperature, as in poly(carbophosphazenes) [802], poly(thiophosphazenes) [803], or poly(thionylphosphazenes) [804]. Another approach is to combine the properties of both the phosphazene backbone and the poly- or oligosiloxane side chains [805], [806], [807].

In the late 1990s a new method for the direct synthesis of organo-substituted polyphosphazenes at ambient temperature has been developed [808], [809]. This route facilitates the control of the molecular mass and provides products with a narrow molecular mass distribution.

6.4.3. *Producers and Markets*

In 2003, only two firms are known to be producing commercial quantities of polyphosphazenes: Ethyl Corp. (Eypel F and A) and Atochem (Elf Acquitain, Orgaflex AMF). Both firms are reported to have pilot plants producing some 25 – 50 t of raw polymer annually [810].

In the past the high price of these elastomers has restricted their use to very specialized applications. New developing markets may be envisioned in which biocompatible, biologically active, or biodegradable polymers are required [811-814], e.g., photo or radiation cross-linkable polyphosphazene compounds for encapsulating biological active materials [815-817, 827, 828]. Novel applications are as materials for flame retardant polymers [818-820], membranes [821-826] and as solid solvents for ionic conduction in rechargeable batteries [829-838]. However, no application is so fast growing at the moment that any expansion of production capacities is announced.

7. Thermoplastic Elastomers

Stephen D. Pask, Andreas Ostrowicki, Bernd Stollfuss

7.1. Introduction

Although thermoplastic elastomers are not synthetic rubbers, and are not dealt with in the introduction or in the market analyses of this article, they compete with synthetic rubbers for a variety of applications. The purpose of this chapter is simply to give a brief overview of these materials since thermoplastic elastomers are treated in ⟶ Thermoplastic Elastomers.

7.1.1. *Definition*

Thermoplastic elastomers (TPE) are polymer-based material that can be processed like thermoplastics at elevated temperature, using conventional processes (such as injection molding, extrusion, blow molding), and exhibit elastomeric properties at their use temperature.

Thermoplastic processing behavior is attained by reversible or chemical cross-linking, such as:

Block copolymer association (glassy or crystalline domains)
Random copolymer segment association
Site association
Chemical bonding

The elasticity of the TPE results from the combination of physical cross-links and entanglements between the rubbery chains or is the result of a heterogeneous dispersion of the rubber phase in semicrystalline thermoplastics ⟶ Thermoplastic Elastomers – Morphology.

Materials ranging form soft rubbers to low-modulus thermoplastics are marketed as TPE, which makes a precise definition of this term diffilcult. However, the following groups of materials can be identified in terms of the basic chemistry involved:

1. PVC blends
2. Styrene block copolymers (SBC), e.g., styrene – butadiene – styrene coplymers (SBS), styrene – isoprene – styrene copolymers (SIS), styrene – ethylene/butene – styrene copolymers (SEBS)
3. Non-cross-linked thermoplastic elastomeric alloys (TPEA)
   - Thermoplastic polyolefin rubbers (TPO), mostly blends of PP and EPM
     - Physically blended (compounded) TPO (CTPO)
     - Reactor TPO (RTPO), produced directly in polymerization reactors.
4. Partially or fully cross-linked elastomeric alloys (EA) or dynamically vulcanized alloys (DVA), i.e., thermoplastic vulcanizates (TPV)
   - Olefinic TPV-based EPDM – PP blends (O-TPVs)
   - Natural rubber – polyolefin TPVs (NR-TPV)
   - Nitrile rubber-based TPVs (NBR-TPV)
   - Butyl rubber-based TPVs (IIR-TPV)
5. Thermoplastic polyurethanes (TPU)
6. Copolyesters (COPE)
7. Copolyether- or copolyesteretheramides (COPA, PAE)

Essentially, the mechanical properties at service temperatures of all TPE depend on a physical cross-linking mechanism that, at processing temperature, breaks down and allows the material to flow. The detailed processes are, however, specific to individual materials. An overview of the different classes of materials and some key properties are shown in Figure 27, a comparison of properties of TPE is given in Table 51.

Figure 27. Thermoplastic elastomers — an overview

⟶ = special grades exist that have an even better performance

Table 51. Comparison of properties of TPEs

TPE	Hardness (Shore)	300 % Modulus, MPa	Tensile strength, MPa	Hard block T_m, °C	Soft block T_g, °C	Service temperature, °C	Oil resistance
SBS	60A – 95A	2 – 6	20 – 32	80 (T_g)	– 90	– 70 – 80	poor
TPO	45A – 75D	7 – 14	7 – 25	140 – 160	– 60	– 50 – 120	poor
TPU	70A – 75D	8 – 35	35 – 45	190	– 20 to – 45	– 40 – 120	good
COPE	90A – 70D	8 – 28	7 – 55	180	– 50	– 50 – 150	good
COPA	60A – 75D	15 – 30	21 – 50	120 – 275	– 50	– 40 – 80	good

7.1.2. *Global Market*

A detailed market analysis of TPE is made difficult by the numerous smaller companies compounding the base materials — such as simple polyolefin blends, SBC, and NBR – PVC — to produce customer-specific and captive use compounds. However, the trends and a prognosis for the near future can be seen in Figure 28.

Figure 28. World TPE market [903]

The worldwide TPE growth rate from 1994 to 1999 is predicted to be 5 – 6 % annually according to the IISRP: More detailed analyses suggest that the growth rates for different classes of TPEs could vary considerably. The consumption figures for different types of TPE in Europe for 1991, 1995 and 2000 are listed in Table 52, together with the annual growth rate.

Table 52. Consumption of TPEs in Western Europe by product classes

Type of TPE	Year 1991	1995	2000	Annual growth rate, %
SBC	117	145	165	2.5
TPO	79	90	121	6
TPV (TPEA)	20	24	41	11
TPU	32	52	67	5
COPE	8	12	20	10
COPA	4	5	7	5
Total	260	329	421	5

An estimated breakdown of the TPE market in terms of end use is given in Table 53:

Table 53. Breakdown of the TPE market in terms of end use

Application	Year 1995	2000
Automotive	30	34
Wire, cable	4	5
Shoe industry	13	10
Polymer modification	11	11
Tubes, hoses	3	3
Modified bitumen	12	11
Construction materials	2	2
Adhesives	10	9
Medical goods	1	2
Films, sheets	2	2
Others	3	3

7.2. PVC Blends

Blends of polyvinyl chloride (PVC) and nitrile rubber have been described in the patent literature since the early 1940s and have been the subject of many reviews [839]. PVC is often added to NBR in conventionally cross-linked systems to impart ozone resistance. In a 1 : 1 mixture of PVC and NBR, both with a molar mass of ca. 1×10^5 g/mol, PVC is completely miscible with NBR containing between 35 and 41 % acrylonitrile [840]. More recently, specially developed NBR, more or less precross-linked, has become available for mixing with PVC at levels of 20 – 80 % to produce thermoplastic elastomer compounds.

The addition of NBR to PVC compounds lowers the compression set, increases abrasion resistance, improves low-temperature flexibility, increases fuel and oil resistance, and improves flex- and cut-growth resistance. Comparison with other TPE and with conventional elastomers [841] show, however, that NBR – PVC blends have a considerable compression set and that their properties deteriorate at higher temperature.

The majority of PVC – NBR thermoplastic elastomers are compounded in-house for captive use. An exception to this is Denka LCS, an improved blend sold by Denka (Denki Kagaku Kogyo Kabushiki Kaisha); some of its properties are given in Table 54 [842].

Table 54. Some properties of Denka LCS

Property	Grade Z-6050	Z-6060	Z-6070
Hardness(JIS K 6301), JISA	50	60	70
Tensile strength(JIS K 6723), MPa	11	13	14
Ultimate elongation(JIS K 6723), %	440	420	400

22 h at 70 °C	39	39	38
70 h at 100 °C	52	49	49
Specific gravity	1.12	1.14	1.15

7.3. Thermoplastic Polyurethanes

Polyurethane thermoplastic elastomers (TPU) were one of the first types of TPE to be commercialized, coming on the market in the 1950s. Because of their high strength and abrasion resistance they are used in a variety of applications from ski boots to cable sheathing. An excellent review of these materials is given in [843]. Thermoplastic polyurethanes consist of linear multiblock copolymers with soft segments having low T_g that are separated by hard segments forming semicrystalline domains and providing dimensional stability. In addition to the incompatibility of the hard and soft domains, interurethane hydrogen bonding promotes phase separation and is, at least in part, responsible for typical TPU properties. Phase separation is, however, incomplete [844-848]: The more nonpolar the soft segment, the greater is the degree of phase separation.

Soft Segments. Of the wide range of possible starting materials only a small number are of commercial interest. Some commercially important polyols and the corresponding T_g of the soft domains in TPU are given in the following:

Poly(ethylene adipate)	–25 °C
Poly(butene-1,4 adipate)	–40 °C
Poly(ethylene butene-1,4 adipate)	–30 °C
Poly(hexamethylene 2,2-dimethylpropylene adipate)	–30 °C
Polycaprolactone	–40 °C
Poly(diethylene glycol adipate)	–30 °C
Poly(hexanediol-1,6 carbonate)	–30 °C
Poly(oxytetramethylene)	–80 °C

The molar mass of the glycols used is normally between 600 and 4000 g/mol. Under normal conditions the crystallization of soft segments occurs only at very low levels of hard segment or after tempering, but it is important in terms of stress-induced crystallization, which leads to self-reinforcement of TPU under load [849].

Hard Segments. The hard segments in TPU are formed from diisocyanates and chain extenders. In addition to the most important diisocyanate, 4,4′-methylenediphenyl diisocyanate (MDI), a number of other *isocyanates* are used as raw materials for TPU [843], [850-853].

4,4′-Methylenediphenyl diisocyanate (MDI) [101-68-8]

Hexamethylene diisocyanate (HDI) [822-06-0]

$OCN–(CH_2)_6–NCO$

1-Isocyanato-3-isocyanatomethyl-3,5,5-trimethylcyclohexane (isophorone diisocyanate, IPDI) [4098-71-9]

4,4 ′-Diisocyanatodicyclohexylmethane (H_{12}-MDI) [5124-30-1]

3,3′-Dimethyl-4,4′-biphenyl diisocyanate (TODI)

2,4- and 2,6-Toluene diisocyanate (TDI) [584-84-9]

1,5-Naphthalene diisocyanate (NDI) [3173-72-6]

The most important *chain extenders* which, together with the diisocyanate, determine the characteristics of the hard domains in TPU are ethylene glycol, 1,4-butanediol, 1,6-hexanediol, and hydroquinone bis(2-hydroxyethyl) ether.

Thermoplastic polyurethanes are prepared by mixing the ingredients at high temperature using either the so-called one-shot method (⟶ Polyurethanes) or the prepolymer method (⟶ Polyurethanes – Reactive One-Pack Systems), whereby the polyol and the diisocyanate are reacted to give a prepolymer before the chain extender is added. Both processes are carried out commercially by using either reaction extruders or a “belt process.” In the latter, the mixed ingredients are poured onto a belt and allowed to solidify before either being chopped directly into pellets or being blended and pelletized.

The ratio of diisocyanate to the sum of the groups which can react with the isocyanate is critical for the properties of the final product; at less than 0.96 the molar mass of the products falls below ca. 40 000 g/mol and its properties are inadequate [854]; at a ratio greater than 1.1, cross-linking occurs and processing becomes more difficult.

Thermoplastic polyurethanes are available in the Shore hardness range 75 A to 75 D. The *properties* of an ester, an ether, and a special ether – ester type TPU of medium hardness are summarized in Table 55.

Table 55. Some typical properties of ester, ether, and ether – ester TPU

Property	Type of TPU		
	Ester	Ether	Ether – ester
Hardness (DIN 53 505)			
Shore A	92	93	96
Shore D	44	42	56
Tensile strength, MPa	45	40	40
Ultimate elongation (DIN 53 504), %	450	380	400
Tear strength (DIN 53 515), kN/m	90	90	110
Abrasion loss (DIN 53 516), mm^3	30	25	35
Compression set (DIN 53 517), % (24 h at 70 °C)	60	60	50
Density, g/cm^3	1.23	1.14	1.20
Stability against*			
Weathering	+	0	+
Hydrolysis	0	+	+
Microbial attack	+/–	++	++

* ++ excellent, + good, 0 mediocre, – poor, +/– sometimes good, sometimes poor.

Thermoplastic polyurethanes can be *manufactured* by most producers of polyurethane resin. The major producers of TPU with dedicated capacities and trade names are given in Table 20.

Table 56. Major world TPU producers

Producer	Capacity, 10^3 t/a	Trade name
B. F. Goodrich	24	Estane
Bayer (Miles, United States)	23	Desmopan (Texin)
BASF (Elastogran)	24	Elastollan
Others	28	

7.4. Styrene Block Copolymers

Styrene block copolymers represent the largest volume of TPE on the market. Their ability to be extended with both oils and fillers has increased their range of applications so that they are now used both as thermoplastic elastomers (e.g., in shoe soles) and as sealants, coatings, and asphalt modifiers.

These materials are composed essentially of three blocks — styrene – rubber – styrene — whereby the central rubber block is either polybutadiene (B), polyisoprene (I), or hydrogenated polybutadiene. The latter, depending on detailed polymerization conditions, leads to a copolymer block that can be identified formally as a copolymer of ethylene and butene (EB). Thus, the three major types of SBC are abbreviated by the letters SBS, SIS, and SEBS. More complex structures, such as star-shaped $(S\text{-}B)_3$ or $(S\text{-}B)_4$ are also available commercially. In all types, the two phases form separate domains at service temperature. Thus, at room temperature, the rubber domains are physically cross-linked by the polystyrene domains, and the proportion of the two phases determines the hardness (stiffness) of the material. The phase separation is better with SEBS so that the service temperature limit is closer to the T_g of simple polystyrene (ca. 100 °C). These hydrogenated polymers are also less susceptible to aging, which allows them to be used for more demanding applications. In particular, the purity with which these materials can be manufactured is leading to increasing use in medical and food packaging applications [855]. Typical properties for an SBS, an SIS, and an SEBS material are given in Table 57.

Table 57. Typical properties for linear SBS, SIS, and SEBS [856]

Property	SBS	SIS	SEBS
Tensile strength, MPa	32	20	34
Elongation, %	880	1200	500
Set at break, %	10	10	
Hardness, Shore A	71	52	75
Specific gravity	0.94	0.93	0.91
Styrene – rubber ratio	31 : 69	21 : 79	29 : 71

Production of SBS and SIS. Block copolymers based on styrene and butadiene or isoprene are manufactured essentially by three processes:

1. Bifunctional initiator process
2. Three-stage sequential addition
3. Coupling process

The *bifunctional initiator process* uses initiators such as sodium naphthalene or organo-dilithium compounds, with the latter generally being preferred [857]. Although initiation with dilithium compounds leads to materials of very narrow molar mass distribution, the limited solubility of the lithium initiators in nonpolar solvents restricts the process to polar solvents such as ethers. In these solvents, butadiene polymerizes anionically mainly by a 1,2-addition process, and the T_g of the polymer rises. This difficulty can be surmounted by adding small amounts of polar solvent to nonpolar hydrocarbon solvents in which butadiene polymerizes mainly via 1,4-addition [858].

The *three-stage sequential addition process* involves polymerizing first a styrene block, then a butadiene (isoprene) block and finally another styrene block. The process is generally carried out by using hydrocarbon-soluble organolithium initiators (e.g., *n*- or *sec*-butyllithium) in hydrocarbon solvents (e.g., cyclohexane, benzene, toluene, hexane). This process is very effective for producing pure block copolymers but is limited to linear polymers [859].

In the *coupling process* the first two stages are identical to those used for a three-stage sequential addition, but the final stage is a coupling reaction. Here the living polymer chains are reacted with di- or multifunctional reagents, such as silanes [860], haloalkanes [861], esters [862], [863], or divinylbenzene [864]. The advantages of this method lie in the ability to produce not only linear but also radial (star) polymers; the precise control of stoichiometry required in the coupling reaction is the major disadvantage.

For all three methods the reaction system must be controlled carefully to exclude impurities, since the presence of homopolymer and especially diblock polymers leads to a deterioration in the properties of the final products.

Production of SEBS. The hydrogenation of SBS polymers to SEBS is usually carried out on polymers containing a large amount of 1,2-double bonds (≥ 40 %). Selective hydrogenation of the resulting diene segments is achieved by carrying out the hydrogenation at low temperature (ca. 35 – 150 °C) using cobalt or nickel acetyl acetonates as catalyst that are reduced with alkylaluminum compounds in situ. A typical solvent is cyclohexane, and the reaction time is usually <4 h between 1.7 and 10 MPa [865-867].

Economic Aspects. Some 50 % of the world market for SBC is supplied by Shell under the trade name Kraton. Shell's total capacity according to several commercial studies is ca. 200 000 t/a. Shell is the only producer of hydrogenated grades with a capacity for these grades of some 40 000 t/a. According to various sources, this capacity is being expanded, and Enichem Elastomeri is expected to be producing hydrogenated grades commercially by the end of 1992 . Other major producers of SBC include Firestone (32 t/a), Enichem (120 t/a), and DOW – Exxon (32 t/a). However, much of the material, based on SBC, that actually reaches the end user as a TPE has been compounded by smaller companies with fillers, oils, or other polymers to achieve materials having an optimum price – property ratio.

7.5. Thermoplastic Polyolefins

Three groups of materials are included under the term thermoplastic polyolefins: (1) simple (compounded) blends (sometimes abbreviated CTPO); (2) reactor-modified polyolefins (abbreviated RTPO); and (3) partially or fully vulcanized blends (TPV).

Thermoplastic Blends. Thermoplastic polyolefins are polypropylene (PP)-based compounds with sufficient elastomer content to impart partial elastomeric qualities to them. As regards production volume, these PP-based elastomers are among the fastet-growing types of thermoplastic elastomers. Some 70 % of the total TPO volume consists of compounded materials, largely blends of partially crystalline polypropylene (homopolymers or copolymers) and amorphous or,semicrystalline ethylene – propene copolymers (EPM or EPDM). As simple blends, their morphologies depend not only on the viscosities and properties of the base polymers, but also on the manufacturing process. With 20 – 80 vol % rubber the blends usually have a continuous rubber phase and often comprise two cocontinuous phases.

The use of EPM or EPDM with a certain proportion of crystalline ethylene units increases the tensile strength and elasticity at room temperature, but these improvements are lost at higher temperature (> ca. 70 °C). In addition to a large number of proprietary materials [868], many end users are now compounding their own blends for their specific needs since further compounding of the proprietary blends is usually not successful. Work to expand the property range of PP-based elastomers centers on improved performance of the elastomer phase. By upgrading the blendability of these rubbers or using different elastomers, suppliers can produce TPOs with a wider range of properties. For example, ethylene – α-olefin copolymers, produced by Dow's Insite metallocene process, are said to be more miscible with PP than EPM and to provide up to 20 % higher cold-temperature impact strength than equivalent contents of EPM in the blend. These metallocene-catalyzed polymers also provide more rigidity to a TPO than EPM, because of their crystallinity of 10 to 15 % (the crystallinity of EPM is only 0 to 5 %).

The rather poor elasticity of these simple blends can be improved by *partial cross-linking* of the rubber phase during mixing with, e.g., peroxides [869], [870]. The action of peroxides leads to a reduction in the molar mass of the PP and probably also to some grafting.

Both simple blends and partially cross-linked systems can be filled with inorganic fillers and extended with oil.

In the 1990s *blends of natural rubber* (*NR*) *and PP* have become available commercially [871]. In these systems the PP appears to provide some protection for the NR against oxidation, while the double bonds in NR can still be used to prime the article surfaces ready for painting or bonding. These systems also appear to show some strain-induced crystallization typical of NR. The properties of two commercial NR – TPO products are given in Table 58.

Table 58. Properties of two NR – TPO products [871]

Property	Telcar Z 1189	Vitacom 7001
Hardness Shore A	56	70
Tensile strength, MPa	4.0	9.8
Elongation, %	290	320
Compression set, %		
22 h at 70 °C		37
22 h at 100 °C	43	44

Because of the nature of the supply (i.e., a large number of small compounders, several hundred worldwide) and because a considerable quantity of material is prepared for captive use, a breakdown in terms of suppliers of these materials is not only difficult but also of doubtful reliability.

Thermoplastic Vulcanizates. If nonradical cross-linking systems are employed, the rubber phase in a TPO can be essentially completely cross-linked while a thermoplastically processible material is maintained (dynamic vulcanization, see below).

Typical cross-linking systems for TPV are phenol – formaldehyde resins, metal halides, and zinc oxide [872]. Since the original patent of GESSLER [873], CORAN and PATEL have developed the idea of producing materials from most rubbers and a range of thermoplastics [874-880]. In contrast to the simple and partially cross-linked systems, these fully cross-linked systems have a fixed morphology, and their properties are less sensitive to additional processing steps. Indeed, such materials can be reworked several times without the loss of properties [881]. The morphology of TPV comprises small (ca. 1 – 5 µm particles of cross-linked rubber in the thermoplastic matrix, even up to rubber contents of ca. 80 – 90 vol %. The rubber volume can be extended with considerable amounts of mineral oil and the entire blend filled with inorganic filler.

Commercially, the most successful TPV (based on EPDM and PP) is marketed by Advanced Elastomer Systems (capacity probably ca. 60 000 t/a) under the trade name Santoprene. For applications demanding better oil resistance, Advanced Elastomer Systems markets a TPV based on nitrile rubber and PP under the name Geolast. The hot-oil resistance (≥ 120 °C) of this TPV is, however, not as good as that of an NBR vulcanizate because of the lack of resistance of the PP matrix.

A comparison of the properties of simple blends, partially cross-linked TPO, and TPV is given in Table 59.

Table 59. Comparison of the properties of different types of EPDM – PP TPO

Property	Simple blend	Partially cross-linked blend	Fully cross-linked TPO

Compounding thermoplastics and rubbers can be carried out either in Banbury mixers, provided they are constructed for the higher temperatures necessary (ca. 200 – 240 °C) compared to those normally encountered in rubber compounding, or in continuous mixing machines [882], [883]. Dynamic vulcanization essentially involves adding the cross-linking chemicals after the polymers have been mixed and continuing the mixing until the cross-linking reaction is complete. Although this reactive processing can be carried out in Banbury mixers, the mixing times are inordinately long (10 – 20 min) so that continuous mixers are employed commercially and running temperatures are increased (for EPDM – PP blends, 220 – 240 °C) to reduce the time required to complete cross-linking [882].

Reactor-modified thermoplastic polyolefins are based on relatively new technology, but due to the cost advantage they represent a very dynamic market. Besides being used alone, they can be used, for example, to modify PP to produce a new generation of TPO. Major areas of application are in films, hoses, and automobile trims.

These materials are produced by gas-phase polymerization using modified Ziegler catalysts and gas-phase, fluidized-bed technology [884]. The most widely known process is probably that licenced by Union Carbide under the trade name Unipol [885], [886] (⟶ Polyolefins). Polymers are sold under the trade name Flexomer. Exxon Chemicals (trade name: Exxtral) is said [887] to have its own catalyst technology, and Montecatini (Himont) has its own process called Spheripol (polymer trade name Spherilene).

7.6. Copolyesters

The copolyesters were commercialized in the early 1970s by Du Pont under the trade name Hytrel [888] and by Toyobo [889] under the trade name Pelprene. They have often been referred to as engineering thermoplastic elastomers because of their high flexural modulus. Because of their excellent processibility, rapid crystallization rates, and broad range of physical properties (see Table 60), these materials are widely accepted for component integration in the machine and automotive industries. Of particular interest is their “perfect spring” behavior at low elongation: up to 7 % for the stiffer materials and 25 % for the softer grades. The service temperature range for COPE (– 40 to + 150 °C) is wider than that of TPU [890], [891].

Table 60. Some properties of COPE [894]

	Hardness (Shore D)

Melting point, °C	106	189	189

These multiblock thermoplastic elastomers are *synthesized,* for example, from dimethyl terephthalate, poly(tetramethylene ether) glycol, and tetramethylene glycol via a transesterification reaction in the melt using titanium catalysts [892]. During the final stage of polymerization, excess short-chain diol is removed by distillation. The lower the reaction pressure, the faster is the rate of polymerization, as measured by the increase in inherent viscosity. Other monomers are also used [893] to produce a family of materials whose multiblock structure — with hard segments composed of crystalline poly (tetramethylene terephthalate) and soft segments composed of poly(tetramethylene ether terephthalate), for example — is analogous to that of TPU (see Section Thermoplastic Polyurethanes) and polyetheramides (see Section Copolyether- and Copolyetheresteramides).

A more recent, detailed review of this class of materials can be found in [895].

The major *supplier* of COPE worldwide is Du Pont, which also produces material in Japan in a joint venture with Toray. General Electric (Lomod) and Hoechst – Celanese are the major competitors for the world market of some 40 000 t/a. Detailed capacities could not be ascertained.

7.7. Copolyether- and Copolyetheresteramides

The polyether(ester) – polyamide block copolymers, often abreviated generally as PEBA [896], [897], have similar multiblock microstructure to TPU and COPE (see Sections Thermoplastic Polyurethanes and Copolyesters). In copolyetheramides (PEA), the *soft segments* are derived from aliphatic polyesters, whereas in copolyetheresteramides (PEEA) the soft segments are derived from aliphatic polyethers linked to the hard segments via an ester moiety. The *hard segments* can be formed from aliphatic or aromatic amides.

Depending on the amide type the hard segments are either glassy or semicrystalline. These segments also control the high-temperature properties of this class of TPE. The physical properties of these materials are similar to those of COPE, but these amide systems generally exhibit lower hardness (> ca. 60 Shore A), lower moduli, and significantly lower specific gravity (typically ca. 1.01, compared to 1.15 – 1.22). Compared with COPE, PEBA polymers have a smaller service temperature window (– 40 to 80 °C [898]). Those types based on highly crystalline aromatic amides can have good mechanical properties up to ca. 170 °C continuous use [899]. They find application, for example, in gaskets and seals, conveyor belt rollers, tubes and hose, shoes, and medical uses.

Two approaches are used for the *synthesis* of block polyamides: via a *polycondensation* of aromatic diisocyanates with dicarboxylic acids as chain extenders to give the hard amide blocks and a carboxylic acid-terminated polyester or polyether for the soft segments. Typically MDI is the diisocyanate, and adipic or azelaic acid is used as chain extender. The prepolymer soft segments generally have molar masses in the range 500 – 5000 g/mol [900], [901]. Alternatively, the carboxylic acid-terminated polyamide blocks can be synthesized from polyamides using dicarboxylic acid chain limitors at $T \geq 230$ °C and $p \geq 25$ bar. The hydroxyl-terminated polyethers are produced either anionically or cationically from ethylene and propylene oxides or from tetrahydrofuran, respectively. Finally, a *polyesterification* is carried out at 230 – 280 °C under reduced pressure [896], [902].

The major *producers* of polyamide TPE are DOW (Estamid) and Atochem (Pebax). Typical *mechanical properties* of these materials are given in Table 61.

8. Evaluation of the Present Situation and Remarks on Future Trends

Desmond Threadingham, Werner Obrecht, Rüdiger Engehausen, Wolfgang Wieder, Gerhard Wachholz

8.1. Market, Producers, and Capacities

8.1.1. *Market*

Basically two sources of statistical data on rubber production and consumption exist: The London-based IRSG (International Rubber Study Group) and the IISRP (International Institute of Synthetic Rubber Producers), based in Houston, Texas [1238], [1239].

The IRSG is an intergovernmental organization of 17 member states. The strength of the IRSG market data lies in its coverage of NR. The information on SR, however, is less precise, as the data also includes some thermoplastic elastomers such as SBS, SIS, and SEBS and latices [1240]. A differentiation is not always made between carboxylated and noncarboxylated SBR latices. This is crucial insofar as some countries classify carboxylated latices as plastics.

The IISRP is an association of synthetic rubber manufacturers. Approximately 95% of total SR production is now documented by the IISRP, because the Chinese manufacturers also joined this organization. Some of the Russian producers and a few smaller manufacturers in Central Europe and Asia are still absent.

The IISRP publishes data on NR and SR, with the IISRP statistics being characterized by data on individual SR types. In order to have clear distinctions for SR, several years ago the IISRP decided only to publish consumption data on solid rubbers. The only exception is CR which includes a small proportion of latex. For these reasons, the following observations are limited to the solid rubbers, i.e. solid NR and solid SR.[1)]

The trend in rubber consumption in the final decade of the last century was marked by a significant downturn in the early 1990s. (see Fig. 29).

Figure 29. Global consumption (10^3 t) of solid rubber (NR, SR) 1990 – 2000

The collapse of the Communist system in Eastern Europe, and in the Soviet Union in particular, resulted in an economic decline which also significantly affected rubber consumption in this region up until 1994. Superimposed on this trend were the negative after-effects of the Gulf war with a global economic crisis which did not end until 1993.

Development in rubber consumption was correspondingly weak until 1993. From that point onwards, worldwide rubber consumption grew at an annual rate of 3.5% until 2000. Even the Asian crisis in 1998 only stemmed this growth temporarily. The growth in rubber consumption was particularly strong in North America (excluding Mexico) and in the Asian countries, especially China (SCA). China managed to more than double its rubber consumption over this 10-year period.

While worldwide SR consumption only increased by 0.7% p.a. in the 1990s, NR consumption grew by 3.3% per annum (Table 71).

Table 71. Growth in NR and SR consumption, 1990-2000

	1990	1991	1992	1993	1994	1995	1996	1997	1998	1999	2000	CAGR* (90/2000)

NR Solid, 10^3 t	4.614	4.498	4.759	4.784	5.025	5.259	5.364	5.652	5.777	5.835	6.380	3.3 %
Total, 10^3 t	12.910	12.247	12.373	12.000	12.363	13.046	13.411	14.008	14.058	14.436	15.267	1.7 %

*CAGR: Compound Annual Growth Rate

Worst affected by the economic decline in Eastern Europe (EE) in the early 1990s was SR. The USSR had built up enormous polyisoprene capacities for strategic reasons, in order not to be dependent on NR.

In 1990, NR represented only 9% of total rubber consumption in EE, compared with 30% in North America (NA) and 37% in Western Europe (WE), not to mention the Asian countries, in which the percentages were much higher.

Even in 2000, NR represents only 20% of total rubber consumption in EE (Table 72). The increase compared with 1990 is attributable not so much to a structural adaptation of the rubber-producing industry as in the West, but to SR consumption itself, which is still very low and has not yet reached its previous level. It was not until the end of the 1990s that SR consumption took off as a result of the economic recovery in the Russian Federation.

Table 72. Ratio of solid SR to NR consumption by major region, 2000

	NR Solid	SR Solid
EE	20 %	80 %
NA	33 %	67 %
WE	38 %	62 %
As/Oc	51 %	49 %
SCA	53 %	47 %
World	**42 %**	**58 %**

It remains to be seen whether Russia will make full use of the remaining IR capacities. A short supply of NR in the coming years coupled with increasing prices could create the conditions for further activation of the IR plants.

As expected, NA leads the world with a per capita rubber consumption of 11.7 kg, with WE trailing in second place followed by the other regions.

Although it would clearly be wrong to use NA as a benchmark for other regions because of its transport structure, Table 73. gives an indication of the long-term potential which still exists in other regions in terms of rubber consumption.

Table 73. Solid rubber consumption per capita by region, 2000

Regions	NR and SR 10^3 t	SR 10^3 t	Population $\times 10^6$	NR and SR per capita, kg	SR per capita, kg
NA	3,694	2,464	316	11.7	7.8

* incl. Turkey
Source: IISRP, IRSG, United Nations Population Division, estimates by the author.

A glance at the growth in individual SR types shows that consumption of tire rubbers (SBR, BR, IR and IIR) almost stagnated (+0.2 % p.a.) between 1990 and 2000 (see Fig. 30). While the former USSR was still consuming large volumes of SR in 1990, the economic collapse led to a drastic decline in the consumption of SR, and the tire rubbers IR and ESBR in particular. The USSR had a large share of world capacity for these rubbers (81% for IR with 1.1 × 10^6 t and 17% for ESBR with 690 x10^3 t) [1241].

Figure 30. Global consumption (10^3 t) of solid SR by category and type

Unfortunately, the IISRP has not published any data on the solution polymerized rubber SSBR, which is subsumed under SBR in Figure 30. SSBR and BR are tire rubbers which have shown consistently strong growth in the 1990s. In many cases, they have replaced ESBR in the tire treads of “green” passenger car tires. Using silica as a filler, Michelin succeeded at the beginning of the 1990s in developing passenger car tires with improved wet grip and lower rolling resistance without reducing the tire lifetime. These tires rapidly became popular, particularly in WE, because of their lower fuel consumption.

Because of its high air impermeability, butyl rubber (IIR) is virtually irreplaceable as a tire component. The transition from tires with tubes to tubeless tires led to a decline in non-halogenated butyl and increased demand for halobutyl rubber. Butyl rubber is now produced by a total of five manufacturers worldwide: Exxon, Bayer, two manufacturers in Russia, and one in China. Exxon and Bayer together have a capacity share of more than 75% [1242].

In contrast to tire rubbers, the nontire rubber market grew by 2.4% p.a. between 1990 and 2000, with EP(D)M showing the strongest growth at 4.3% p.a.. After ESBR and BR, EP(D)M is now the third most important SR type, with a share of 10%. In the past, its growth has been partly at the expense of CR and NBR.

Specialties meet a growing demand for high-tech articles for use in difficult environments and have shown consistent growth. There are about 16 rubbers in this category with outstanding performance properties. Neither the IISRP nor the IRSG provide detailed information on this segment.

After the highest worldwide rubber consumption so far was reached in 2000, consumption fell (-4.3%) in 2001 as a result of the economic crisis (September 11) with declining markets in cars and tires (Table 74).

Source: Estimates by the author based on IISRP and IRSG statistics

Only China (SCA) and EE brought a glimpse of cheer to the generally gloomy picture. At the time this article was written, no definitive data were available for 2002, although there should have been some positive growth again in worldwide consumption.

In the medium term, rubber consumption will continue to grow in the wake of a recovering world economy, although differences between the regions may be very great.

In Europe, the main growth will be in EE. In the long-term, NA will be affected by a shift in tire production to more cost-effective regions, as has already occurred in WE. The same applies to countries such as South Korea and Japan. In the coming years, China will continue to be the main growth market.

The IRSG is forecasting 6.4% growth in worldwide rubber consumption for 2003 compared with 2002 and 4.9% for 2004 over 2003 [1243]. Economic growth in the main industrial countries so far does not really support this optimistic prognosis for 2003.

8.1.2. *Producers, Capacities and Capacity Utilization*

As can be seen from Figure 31, worldwide SR capacity was 11.2 × 10^6 t in 2002 [1242]. Consumption, on the other hand, came to 8.7 × 10^6 t (see Table 74). If it is assumed that no major difference exists between consumption and production, this gives a theoretical utilization rate of 78%. It is important to take into account here the fact that the figures mentioned are nominal capacities. Under the assumption that the operating capacity is approximately 10% lower than the nominal capacity, this gives a utilization rate of 86%. In addition to this, some capacity figures appear to be excessive. This applies to the IR capacities in Russia and Romania, for example, with a total capacity of almost 600 × 10^3 t [1242]. According to a different source, the plants in Romania have already been closed for some years [1244]. The breakdown of capacities into BR and SSBR is also problematic, because both types can be manufactured together with certain thermoplastic elastomers (SBS, SEBS, SIS, etc.) in multi-purpose plants, but big manufacturers only give total capacities.

Figure 31. World capacities (10^3 t) of solid SR by region and product group in 2002 (no specialties included)

A comparison of capacity and consumption in the regions shows that excess capacity exists in NA, WE and EE, whereas insufficient cover prevails in China. Because of its expanding demand, China will continue to build up capacity in the coming years.

Whereas capacities continued to be expanded in the second half of the 1990s, many manufacturers suffered from negative or stagnating market growth in rubber consumption in 2001 and 2002, particularly in the large industrialized countries. In the case of commodities, this led to considerable elimination of capacities in the saturated markets. Expansion continued, however, in the case of products with growth potential or in regions with strong accumulated demand.

- *Ameripol Synpol* closed down a 95-kt ESBR plant in the USA in 2001.
- *DSM* wants to part with its 150-kt ESBR plant in the USA. With the sale of its NBR business (tolling agreement) to Zeon in 1999, the biggest EP(D)M producer focused its activities on EP(D)M. A new 80-kt EP(D)M plant is to be started up in The Netherlands at the end of 2002/beginning of 2003 [1245]. DSM is also planning to build a new 40-kt plant in China [1246].
- *Bayer* ceased production of BR (95 × 10^3 t) in Canada at the end of 2002 and concentrated the production of NBR in WE at the La Wantzenau site in France. Bayer had previously increased its BR/SSBR capacities in the USA and WE by 100 × 10^3 t in total.
- *Goodyear* commissioned a new 110-kt BR/SSBR plant in the USA at the end of 2000. It pulled out of NBR production altogether in 2001 and sold the business to Zeon. In the field of solid rubbers, Goodyear now manufactures only tire rubbers.
- *Enichem* put the spin-off company Polimeri Europa up for sale in 2002.
  The following products at seven sites are affected by this: CR, EP(D)M, ESBR, SSBR, NBR, BR, XSBR/ NCSBR latices and thermoplastic elastomers (SBS, SIS) [1247].
- *Exxon* will commission a 90-kt plant for EP(D)M, plastomers and noval polymers in 2003 [1248].
- *DOW* considerably expanded its capacities in the tire rubber market in the second half of the 1990s through acquisitions and takeovers (Karbochem in 1998, Shell in 1999) and became one of the top ten manufacturers. DOW first became involved in tire rubbers in 1997 with the acquisition of BSL Olefinverbund in East Germany. In 2000, DOW expanded its capacity there by another 60 × 10^3 t BR/SSBR. With the takeover of Union Carbide in 2001, DOW acquired a 90 × 10^3 t EP(D)M plant, which operates using gas phase technology. The plant is being used by the 50/50 joint venture DuPont DOW Elastomers, which is also responsible for marketing [1249].
- *DuPont Dow Elastomers* (DDE) was founded by DuPont and DOW as a joint venture in 1996, with both companies pooling their resources in the field of performance and high performance rubber [1250]. DuPont contributed EP(D)M, CR, CM, CSM, EAM and FKM, while DOW contributed the CM business and the “Engage” product class which is manufactured on the basis of “Insite” technology. This technology, which is based on a special metallocene-type catalyst, was also used for the joint venture's new EP(D)M plant in Plaquemine (1997).
- *Shell* pulled out of the rubber business altogether with the sale of ESBR and BR to DOW in early 1999 and of the TPE business (SBS, SIS, SEBS, SEP), including IR, to a private equity investment firm in 2000 [1250].
- Additional capacities came onto the market in the ASEAN countries and in China. China alone increased its capacities by 200 × 10^3 t BR/SSBR between 1996 and 2002. Taiwan Synthetic commissioned a 100-kt ESBR plant in Nantong at the end of 1998. The first Chinese plant for manufacturing butyl rubber (30 × 10^3 t) was started up in Yanshan in 2000.

These few examples show how the focuses are shifting between the regions and how major manufacturers are reacting in markets where growth is less strong.

As can be seen from Table 75, the capacity of the top ten manufacturers worldwide was 5.536 × 10^6 t in 2002, which represented 50% of the total world capacity of 11.2 × 10^6 t. Compared with the major plastic groups such as polyethylene, polypropylene, polystyrene and polyurethane, the SR manufacturing landscape as a whole is relatively fragmented. At most, a high degree of consolidation exists in individual product groups such as IIR and EP(D)M. Apart from that, there is a large number of manufacturers in fierce competition with each other. The Chinese company Sinopec has now moved up to number seven in the world ranking. As in many other areas of industry, China is going for expansion and will try to make increasing headway on the world markets in the coming years. PetroChina, the other big SR manufacturer in China, and currently ranked number 12, is also set to join the top ten in

the next few years.

Table 75. Top 10 producers of solid SR by capacity (10^3 t), 2002*

Companies	Country	ESBR	SSBR	BR	IR	IIR	EP(D)M	CR	NBR	Total	Share(%)

* no specialties included
Source: IISRP, Worldwide Rubber Statistics 2002
Remark: Capacities of 50/50 joint ventures were assigned in full to the capacity of the leading producer in that segment

SR manufacturers are having to face increasing concentration and globalization on the part of their customers. This is particularly true of tire manufacturers, although it also applies to manufacturers of technical rubber articles, albeit to a lesser extent. The three top tire manufacturers (Michelin, Bridgestone, Goodyear) now control 60% of the world tire market and can thus exert price pressure on their raw material suppliers. They also operate their own SR production plants and are thus only partially dependent on suppliers. Against a background of lower profit margins, restructuring in the SR industry will continue in the future.

8.2. Market Requirements and Impact on Development of Synthetic Rubber

8.2.1. *Tires and Tire Rubber*

Tire manufacturers have optimized the performance of tires further and further in answer to the constantly increasing requirements regarding safety, economy, and ecology. The key targets for improved tire performance are still lower rolling resistance, better grip performance and higher wear resistance. It is always a challenge to optimize the overall performance in this “magic triangle”, taking into consideration that improvement in one property often can lead to deterioration of another [1252-1257, 1289].

The compromise achieved between these characteristics varies from continent to continent. It is interesting to realize the geographic differences in the requirements for passenger car tires.

Requirement:	Good wet grip	Low rolling resistance	Abrasion resistance
North America	moderate	high	high
Europe	high	high	moderate
Japan	high	high	low

In Europe and Japan, tire grip in wet and dry conditions (safety) and low rolling resistance with the associated reduction in gasoline consumption (environmental protection), have the highest priority. In North America, on the other hand, low abrasion values and low rolling resistance are of particular significance.

Since the 1970s the performance of tires has improved dramatically: The rolling resistance has been reduced by 50%, the life of an average passenger car tire has nearly doubled. In the USA, an average tire lasted about 24 000 miles in the early 1970s; by 2000 that figure had become 43 000 miles. Regional differences are also interesting: in Europe, the average life of a passenger car tire is only between 20 000 and 25 000 miles [1258], [1259].

This development was only possible due to improvements in several areas, such as tire design, computer-aided construction, new mixing concepts, alternative reinforcement materials and filler systems, addition of rubber chemicals for optimized faster curing and better protection of the rubber, and, last but not least, optimized rubber grades.

A summary of the situation in the early 1980s is given in [840]. Since the 1980s, various attempts have been made to provide a better balance of these properties such as: Vinyl-BR and vinyl-IR [841-843], S-SBR and S-BR with optimized micro- and macrostructure [844-851], [1261, 1262], Multiblock S-SBR and S-SIBR (“integral rubber”) [843], [852-867], [1262-1265] CR [840], [868], Epoxidized NR [869], End-group-modified S-SBR and BR [870-884, 1266], Rare-earth-based high-*cis* 1,4-BR [885-898], Blends (rubber–filler, rubber–fiber, rubber–thermoplast, and others) [899-923], Rubber–rubber blends [868], [883], [901], [924-945], Low molecular mass compounding ingredients and modified rubber [910], [918], [946-964], HNBR [965-969], Chemically modified carbon black [970-972, 1267], Resin modification [920], [954], Silicate filler in combination with a filler activator [973].

The energy consumption of the tire tread accounts for nearly two thirds of the rolling resistance of a tire [1268]. In the car tire tread compounds, that are used particularly in North America, carbon black is used as the sole filler. Hysteresis is reduced by using modified S-SBR grades which, by coupling with tin compounds or by end-group functionalization, are able to interact better with the filler than unmodified grades of rubber.

This “linkage” of the polymer to the filler restricts chain mobility, leading to reduced hysteresis and lower rolling resistance [1269]. One disadvantage of this approach lies in the poor wet grip characteristics of the tire tread compounds.

In Europe, an alternative approach to formulation has been established in the late 1990s: by using silica as a filler [1270-1274] it is possible to achieve a simultaneous improvement in rolling resistance and wet grip characteristics.

Introduction of a chemical linkage between the filler and the rubber via a silane group also reduces hysteresis [1275, 1276]. It has proved possible to overcome initial deficiencies in the third component of the “magic triangle”, namely abrasion, by incorporating high-cis-polybutadiene, such as Nd-BR (produced using neodymium catalysts) or Co-BR (cobalt catalyst) into the rubber compound.

A new development in *solution rubbers* involves modification of the entire polymer chain. In conventional polymers, which are used in the aforementioned compounds with carbon black fillers, only the chain ends are modified. Additional functionality may also be incorporated into the middle of the polymer chain by means of a coupling agent (e.g., tin tetrachloride). New research results are indicating the way to innovative new tire rubbers, in which the rubber molecule is modified with functional groups over the entire length of the chain. With this type of functionalization, it is possible to strengthen the interaction between filler and rubber [1277, 1278].

The polymerization processes of E-SBR and S-SBR are different. Coupling and end group modification cannot be carried out in the radical polymerization to form E-SBR. Therefore, other approaches are necessary to introduce functional groups into the E-SBR [1279, 1280]. By using monomers with polar side groups, it is also possible to obtain functionalized polymers in the emulsion process. Using acrylonitrile as a termonomer in addition to butadiene and styrene, a terpolymer, NSBR, can be obtained. In production of NSBR the monomers are polymerized statistically. Usually the ACN content is up to 20% [1281, 1278]. This NSBR shows very good wet grip properties and can be used both in the footwear industry — especially in sports shoe applications — and in tire treads as a wet grip improving agent.

One development in the tire polymer area is the evaluation of the suitability of different nonaromatic oils, such as MES (medium extracted solvate) or TDAE (treated distillate aromatic extract) instead of the standard aromatic DAE (distillate aromatic extract) oil for rubber-like SBR and BR [1282-1285].

Sidewall Performance. Flex cracking and weather and fatigue resistance are important criteria for tire sidewall performance. Compounds consisting of NR – BR blends provide the state-of-the-art solution to these technical requirements, the composition has not changed much since the 1980s. Nd-BR-based compounds exhibit advantages over other BRs (Li, Ti, Ni, Co) [974].

Inner Liners. Increasing performance requirements for inner liners refer primarily to ease of processing, improvement in covulcanization, impermeability, heat and dynamic resistance, and low weight. These requirements are met by a preferred usage of BIIR to CIIR. BIIR-related improvements refer to products with broader molar mass distributions and to brominated rubber grades which are based on isobutene – para-alkylstyrene feedstocks. [1286, 1287-1288], [985-999].

8.3. Production Processes

The present status of SR production and trends in technology are elucidated by review of the patent literature (see Tables 69 and 70). In Table 69 the patent literature is ordered according to chemical and technological features of the key reactions applied to SR production. In Table 70 the literature is categorized according to references that describe improvements of process steps.

Table 69. Literature on synthetic rubber production processes relating to chemical and technological features of key reactions

Chemical mechanism	Type of process for key reaction				
	Emulsion	Solution	Dispersion (slurry)	Bulk	Gas phase
Radical polymerization	[1012], [1013], [1081], [1084], [1117-1125]	[1126-1129]		[1180-1182]	
Ziegler – Natta polymerization	[976]	[957], [958], [967], [969], [970], [1073-1075], [1085],[1134-1141]	[1083]	[959-962], [964], [965], [968]	[1188-1191]
Anionic polymerization		[1080]			
Cationic polymerization		[1029]	[1170], [1171]		

Table 70. Process improvements relating to sequence of process steps for various types of reactions

Process step	Type of reaction			
	Emulsion	Solution	Dispersion (slurry)	Bulk
Makeup of solutions and other components	[1117], [1118]			
Polymerization and polymer modification reaction	[976], [1012], [1013], [1118-1125], [1192]	[966], [967], [969], [970], [1073-1075], [1080], [1126-1129], [1131-1133], [1152-1165], [1170]		[959-965], [968], [1180-1187], [1205-1207]
Short stopping	[1081], [1084]			
Flashing, degassing, and stripping of unreacted monomers, solvents, and other components	[1193]	[1199]	[1175], [1176]	
Postmodification reactions (blending with oil, carbon black, polymers, fibers, etc.)	[972], [993-995], [1009], [1010], [1058], [1072], [1194]		[1177]	
Polymer isolation, cleaning, and drying	[1195], [1196]	[1166-1169], [1200-1202]	[1203], [1204]	
Wastewater treatment	[1197], [1198]			

The patent literature focuses on both well-established and non-state-of-the-art (not yet established) SR technology. *Well-established processes* include radical polymerization in emulsion and solution, as well as polymer modification in solution and dispersion. These processes are reinvestigated for the following reasons:

1. Reduction of environmental impact
2. Improvement of process control and product consistency
3. Reduction of manufacturing costs
4. Production of new products by available technology (in existing plants)

The patent literature dealing with *non-state-of-the-art SR processes* aims at the adoption of readily available technology for the production of close matches for products whose properties are known. Most investigations are in the field of bulk and gas-phase polymerization.

High-pressure bulk polymerizaton using radical initiators is a standard process for production of low density polyethylene. This process has been applied to the copolymerization of ethylene and acrylonitrile [1205], [1206]. It is presently being reinvestigated in order to produce a match for HNBR [1180-1182], [1207] (see Section Hydrogenated Nitrile Rubber).

Recent interest in the bulk polymerization of butadiene by using *Ziegler – Natta catalysts* is a result of the availability of special reactors and captive and market requirements for high-*cis* BR. Ni- [968] and Nd-based [959-966], Ziegler – Natta catalysts are used.

Production of polyethylene, polypropylene, and linear low-density polyethylene by *gas-phase polymerization* is a well-established technology. The obvious problems associated with applying this technology to production of EPDM are the stickiness of the particles formed and the difficult removal of residual ethylidenenorbornene. A U.S.-based firm has apparently tackled these problems and is presently starting up pilot-plant production of EPDM [1208].

A positive impact on SR development can be expected from *Kaminsky – Brintzinger – Sinn-type metallocene alumoxane catalysts* [1130]. Progress in the technological properties of EPDM is reflected in the recent patent literature [1134-1141], [1132], [1133] and papers [1142-1149].

Another breakthrough has supposedly been achieved with the *polymerization of polar monomers* using Ziegler – Natta catalysts. This opens the possibility of SR synthesis by copolymerization of olefins and monomers such as acrylonitrile [1131], methyl acrylate [1150], and vinyl acetate [1151], which have thus far been considered poisons of the active sites of Ziegler – Natta catalysts.

Thus, sufficient know-how exists for a technological “quantum jump” in SR production. Since the SR manufacturing industry faces sluggish market growth and tough competition, investments will be focused on refurbishing existing plants rather than establishing a completely new technology that involves high risks, unless a significant reduction in manufacturing costs can be expected.

8.4. Ecological and Health Aspects

8.4.1. *Introduction*

Environmental and health aspects of rubber extend over the whole life cycle of a rubber part, starting from raw materials and covering all stages of storage, transport, manufacturing, and use. At the end of its life, recycling of the rubber article or its disposal still remains an issue to be solved. Chemical legislation, safety regulations, directives and guidelines apply for each single stage of the article's life, as illustrated by the following list, which reflects the legal situation in Europe, and which is far from being comprehensive. Other regions apply similar legal tools:

Chemicals. Dangerous Substances Directive
Emissions. Integrated Pollution Prevention and Control (IPPC), Ambient Air Quality Management
Water/ Wastewater. Water Framework Directive
Plant safety. Prevention of Industrial Risks Directive (“Seveso Directive”)
Food contact. Framework Directive 89/109/EEC
Waste. Hazardous Waste Directive; Recycling

Special regulations deal with nitrosamines, volatile organic compounds (VOC), transport, etc. Hence, although the risks regarding production and use of rubber parts seem to be manageable, the legal framework necessary to ensure product safety is somewhat complicated and often incoherent.

8.4.2. *Health Aspects*

8.4.2.1. *Raw Materials*

Raw materials for rubber include polymers, rubber additives, processing aids, extenders/plasticizers, fillers, and reinforcing materials, such as steel cord or fibers. Generally, the *polymers* (SR or NR) do not pose health problems within the rubber industry, because trace amounts of residual monomers, e.g., butadiene, styrene, acrylonitrile, or chloroprene are removed during rubber processing. Concerns of sensitive consumers such as food contact, are regulated by laws or directives in some countries. However, some SR *additives or plasticizers* such as aromatic extender oils or phthalates merit special attention. Aromatic extender oils are classified as carcinogens, and some phthalates are teratogenic. No exposure, hence no risk is to be expected during normal handling of extended rubbers, because it has been demonstrated that the extenders/plasticizers are occluded in the polymer matrix and are not bioavailable. In addition, some *rubber chemicals* pose potential health and environmental hazards. Many accelerators and antioxidants are classified and labeled as sensitizers and/or hazardous to the environment. Production, transport, storage, and use of these chemicals are regulated by several directives, hence no risk should be associated with rubber additives when handled under specified conditions. Exposure to chemicals can be minimized by using predispersed or coated products [1290]. One aspect however, which is closely related to the use of accelerators, is the occurrence of nitrosamines. Some of these are proven and potent carcinogens to animals, according to test results. Nitrosamines are generated wherever secondary aliphatic amines are involved (⟶ Rubber, 4. Chemicals and Additives – Toxicology and Ecology of Organic Vulcanization Accelerators). In order to protect workers and consumers, a specific and severe legal framework applies. Guidelines in Germany set airborne limits for carcinogenic nitrosamines [1291], [1291]. Nitrosamine migration from baby teats and soothers is regulated on EU level [1292]. Since for most applications less dangerous accelerators are available, the nitrosamine problem appears to be manageable [1293].

8.4.2.2. *Processing*

Unit operations of rubber processing include raw materials storage, mixing/blending, shaping, vulcanization, and storage of finished articles. Along the whole process, exposure of workers to hazardous substances may occur. Many regulations for industrial hygiene apply, so that in case of occupational exposure countermeasures can be taken. An epidemiological retrospective study on German rubber workers revealed an increased risk of developing cancer [1294], which may have been caused by exposure to aromatic amines, asbestos, solvents, nitrosamines, or curing fumes. Curing fumes have been studied recently [1295]. They consist basically of a great number of organic substances, depending on vulcanization/curing conditions (time, temperature, etc.). Due to the complex nature of the emissions, a risk evaluation is difficult. Different investigations have shown that exposure to curing fumes may slightly increase the health hazard. The findings usually cover a long period of time, thus reflecting the earlier situation when the operating conditions were less developed than today. It can be stated, however, that workplace hygiene has very much improved since the 1980s.

8.4.2.3. *Use*

Consumer contact mainly occurs indirectly, e.g., via food contact. In many countries, food contact regulations exist, which regulate, e.g., compound ingredients or use conditions. Possible migration that might occur between rubber articles and food is strictly limited. Migration of antioxidants into food can be minimized by chemical attachment of the antioxidant to the polymer [1296]. The major use of commercialized rubber parts is in automotive or technical applications where no significant exposure occurs.

Latex protein allergy as a problem for the rubber industry became important with increasing use of gloves and other articles made from NR latex. The allergic reaction is due to a small fraction of residual soluble (extractable) proteins, which may become respirable by powdering the gloves [1297]. It is technically feasible to reduce the content of proteins in latex, so that the protein allergy can be managed. (An alternative is to use synthetic (e.g. XNBR) rubber latex). Skin contact allergy may also be caused by rubber chemicals (accelerators, antioxidants), which are frequently classified as sensitizers.

8.4.3. *Environment*

The production of polymers and rubber additives is subject to emission regulations. Likewise, transport and processing has little impact on the environment. In comparison with other sources, e.g., the traffic, the emission of curing fumes, for instance, contributes only to a very small extent to the pollution in the urban environment [1295]. However, the fate of material resulting from tire abrasion and from waste tires is becoming increasingly important in environmental policy and public interest. In 1998, a comprehensive study of the impact of tire debris was published [1298]. It was shown that rubber chemicals and their metabolites as well as polycyclic aromatic hydrocarbons (PAH) and zinc oxide were detectable in highway run-off water. The concentration of these substances decreased rapidly with increasing distance from the highway. It was concluded that photolytic and oxidative degradation of small abraded particles prevents accumulation of tire additives. Substitution of aromatic oils by safe process oils in tire treads was recommended in order to reduce the environmental impact of tire debris. In 2001 a comprehensive picture of the environmental impact of tires was gained by a life cycle assessment (LCA), where all aspects of a tire were assessed, including energy consumption, raw materials, emissions, and waste disposal [1299]. According to ISO 14040, this was achieved by:

- Compiling an inventory of relevant inputs and outputs of a product system;
- Evaluating the potential environmental impacts associated with those inputs and outputs;

– Interpreting the results of the inventory analysis and the impact assessment in relation to goal and scope;

Based on the study, the following conclusions can be drawn:

The use phase has the highest contribution to the environmental load in the life cycle of a car tire

The most important environmental aspect of car traffic is the fuel consumption that increases with increasing rolling resistance of the tires. Tire debris has a significant contribution to the overall life cycle, but its role is modest in comparison with the fuel consumption

The environmental load in the production phase of a tire is mainly determined by the production of raw materials, and not by the tire manufacturing itself

The average end-of-life scenario has a relatively low contribution to the overall load of the life cycle. Similarly, distribution transport, and end-of-life collection transport has little significance

It is not possible to determine the environmental load of retreaded tires precisely.

8.4.3.1. *Recycling.*

Discarding of rubber products, particularly used tires has caused severe environmental problems in the past. Used tires account for ca. 60% of total rubber waste in Europe. Many attempts to recycle waste tires have been undertaken. Retreading is a proven technology to extend the use phase of tires, but the final problem of end-of-life disposal remains controversial. Several technologies were developed which would allow for recycling of the vulcanized rubber [1300]; e.g., reclaiming [1301], [1302], grinding [1303], and finally incineration in cement kilns which turned out to be the most practical option. In Germany, about 550 000 t of used tires must be managed annually. About 55% are incinerated with energy recovery, retreading accounts for another 30%, and about 10 % are reused after grinding or reclaiming in less demanding applications, e.g., sport ground surfaces. However, toxic eluates may migrate from such surfaces [1304]. In the USA, the major part of approximately 250 × 10^6 scrap tires per year are utilized for tire-derived fuel [1305].

8.4.4. ***Outlook***

In the near future, a more severe regulation of chemical substances along the value chain is expected (“White Paper”). Polymers are less concerned than rubber chemicals and additives, including accelerators, antioxidants, processing aids, etc. The EU White Paper is a starting point for a comprehensive approach to a European substances legislation with the ultimate target to manage all risks to humans and environment regarding the production, use, and discharge of substances, that are produced or imported at volumes > 1 t/a [1306]. The White Paper will result in a regulation, with the REACH process as basis (**R**egistration, **E**valuation, **A**uthorization of **Ch**emicals), in order to assess and manage the risks of a substance through the value chain, which implies that downstream users, e.g. the rubber industry, are involved. The new regulation will replace about 40 different pieces of EC legislation which regulate chemical substances, as well as an amendment to the classification and labeling Directive. Thus, the rubber industry will be affected by some particular features and issues. However, disposal of worn tires remains an issue that requires an economically and ecologically compatible solution. The environmental impact of tires can be improved by substituting aromatic extender oils by safe process oils [1307]. A great progress was made by the development of “green” tires, which significantly reduce fuel consumption without sacrificing safety standard or longevity of the tires [1308].

1. Introduction

Rubber chemicals and additives are essential for the production of rubber-elastic materials. They basically fulfill three functions:

1) They make compounding and processing easier.
2) They determine elastomer properties.
3) They protect the finished product against deterioration in properties under the conditions of use. This broad range of functions explains the large number and variety of rubber chemicals and additives [1 – 4].

2. Vulcanization Chemicals [5 – 9]

2.1. Basics of Vulcanization

Rubber products are characterized by high resilience following mechanical deformation: the original dimension is restored almost immediately after the load has been removed. This rubber elasticity results from a three-dimensional network structure of long-chain rubber molecules that are bonded to one another at cross-linking points (cross-links). Vulcanization is the chemical process of forming these cross-links between polymer chains. The viscous raw rubber, characterized by irreversible Newtonian flow, is converted into the elastomer.

Sulfur and peroxides are used mainly as curing agents; to a small extent, special cross-linking agents may be employed.

The restoring force after deformation is a function of the number of network-forming polymer chains per unit volume. Increasing the number of cross-links distributes tension over more polymer chains and thus increases the restoring force [10].

The vulcanization process can be monitored continuously by using *vulcameters.* The cross-linkable rubber compound is subjected to periodic deformation in a reaction chamber at a given temperature, and at the same time the force or torque necessary to produce deformation is monitored. Basically two types of vulcameters exist that measure linear and torsional shear, depending on the sample deformation [11]. Important industrial parameters can be determined from a plot of the cross-linking or curing isotherm as a function of reaction time (Fig. 1). The *scorch time* t_s (time taken to reach a given increase ΔF above F_{min}) defines the beginning of the cross-linking reaction (onset of cure) and gives information on the flow time and processibility of the compound at a given temperature. The minimum force F_{min} observed correlates with the compound viscosity. Depending on the vulcanization agents chosen, the start of vulcanization can be adjusted to be rapid or delayed. For curing in molds (e.g., in tire production) a longer flow period is necessary for the rubber compound before vulcanization starts, so that the compound can fill all the cavities in the mold perfectly and trapped air can be released. In other vulcanization processes, as in steam curing or ultrahigh-frequency (UHF) vulcanization, a rapid start is desired, so that the onset of cross-linking prevents deformation of articles through the flow processes. Too rapid an onset of cure

Figure 1. Vulcameter curves (for explanation see text)

(or scorching) is undesirable in most cases because the processing safety in compounding and molding is impaired. Scorched compounds can no longer be perfectly extruded or calendered.

The *steepness of the cross-linking isotherm* is a measure of the rate of the cross-linking reaction. Rate constants can be calculated from the reaction times t_x and the corresponding torque F_t. Generally, a very rapid cure rate is preferred. In the region of optimum cure the maximum cross-link density is achieved. The ideal graph of a cross-linking isotherm is a right-angled step function. The final force achieved $F_{\max}$ is a measure of the cross-link density and often correlates with stress values (force per initial cross section required to produce a specific elongation) obtained from static stress – strain tests [12]. In the overcure region the vulcameter force can be constant, can increase (marching modulus), or for certain rubbers (e.g., natural rubber and polyisoprene) can decrease (reversion).

The course of vulcanization can also be followed discontinuously by plotting typical rubber-elastic properties such as stress, tensile strength, elongation at break, elasticity, or tear resistance, against vulcanization time. Individual physical properties reach their optimum at different vulcanization times. For example, elasticity and compression set values are optimal in the region of slight overcure, whereas tear resistance shows maximum values at slight undercure.

Variation of Vulcanizate Properties with Cross-Link Density. Figure 2 shows schematically the dependence of some vulcanizate properties on cross-link density. The static modulus (curve c) increases with vulcanization more steeply than the dynamic modulus (curve b), which is composed of elastic and viscous parts. Vulcanization leads to a shift in the viscous properties in favor of elastic behavior. The hysteresis losses (i.e., the energy converted irreversibly to heat) decrease (curve f). The tensile strength, tear resistance, fatigue life, and toughness are all a function of energy at break (curve a). These properties increase initially with the buildup of cross-links and then decrease rapidly with increasing cross-link density [13].

Variation of Vulcanizate Properties with Structure of Cross-Links. The mechanical properties of natural rubber (NR) vulcanizates are more strongly affected by the structure of the cross-links than those of synthetic rubber vulcanizates. For example, polysulfidic cross-links increase tear and fatigue resistance, while thermally stable carbon – carbon cross-links or monosulfidic ones lead to aging-resistant vulcanizates with low compression set and higher reversion resistance.

Figure 2. Variation of vulcanizate properties with cross-link density
a) Tear strength, fatigue life, toughness; b) High-speed dynamic modulus; c) Static modulus; d) Hardness; e) Tensile strength; f) Hysteresis, permanent set, friction coefficient

2.2. Sulfur-Containing Cross-Linking Agents

Rubber containing carbon-carbon double bonds, such as NR, styrene – butadiene rubber (SBR), butadiene rubber (BR), and nitrile rubber (NBR) is basically still being cross-linked, as in the past 80 years, by using a combination of sulfur, organic accelerators, and activators (e.g., zinc oxide). The annual worldwide consumption of sulfur for the production of elastomeric materials was estimated to be 225 000 t in 1990, and that of organic vulcanization accelerators and sulfur donors to be more than 200 000 t. Sulfur cross-linking accounted for more than 80 % of all rubber cross-linking reactions [14].

Vulcanization with sulfur and accelerators is preferred for several reasons: (1) economics, (2) excellent controllability of the vulcanization rate with accelerators and retarders, and (3) the possibility of affecting the nature of the cross-links by the type and quantity of accelerators and by the amount of sulfur. Polysulfidic cross-links give good elastic properties and high tensile strength to vulcanizates; mono- or disulfidic cross-links yield vulcanizates with good heat resistance.

Completely saturated rubbers, such as ethylene – propylene elastomers (EPM), ethylene – vinylacetate copolymers (EVM), chloropolyethylene (CM), or acrylate rubber (ACM) cannot be vulcanized with sulfur. Other cross-linking agents must be used.

Elemental Sulfur. Sulfur has been known as a cross-linking agent for more than 150 years. C. Goodyear first succeeded in cross-linking natural rubber in the United States in 1839. The patent claims the production of rubberized cotton tissue at 132 °C using 100 parts NR, 20 parts sulfur, and 28 parts $PbO \cdot PbCO_3$ [15]. Although they were part of the formulation, Goodyear did not recognize the cure-activating effect of metal oxides. At about the same time, T. Hancock in the United Kingdom discovered that NR can be vulcanized by dipping it in molten sulfur [16].

Ca. 0.2 – 5 % sulfur (based on the rubber) is added for the production of *rubbery articles*. For *vulcanite*, the proportion of sulfur is increased to 25 – 50 %. The dosage range of ca. 5 – 25 % sulfur is not used for most applications (apart from floor or certain roller coverings), because the vulcanizates produced lie in the leather-hard region and have unfavorable toughness and elastic properties. To be suitable for vulcanization, sulfur should be 99 % pure (ash content <0.2 %). It must be acid free (acid content, max. 0.2 %), because acids retard vulcanization. Flowers of sulfur, which generally contain a significant quantity of acid, are therefore not used often. Sulfur powder, produced by the Claus process (→ Sulfur) with subsequent grinding, is preferred. This sulfur has particle sizes up to 150 µm, classified according to Chancel grade (old method to determine the particle size of sulfur suspended in ether) [17] and can be distributed readily in rubber compounds. Uniform distribution of sulfur is a prerequisite for a good property profile of rubber. At low sulfur dosages or in rubbers in which sulfur cannot readily be distributed homogeneously (e.g., NBR), sulfur treated with dispersion agents or sulfur pastes are frequently applied.

If so much sulfur is added to the compound that its solubility limit is exceeded, common sulfur tends to bloom on the surface, which makes adhesion or welding during assembling more difficult. Blooming can be avoided by using *insoluble sulfur* (sulfur containing 95 – 97 %

highly polymerized molecules that are insoluble in carbon disulfide). The insoluble sulfur (particle diameter 2.5 – 3.5 µm) is much finer than sulfur powder and is mixed with mineral oil plasticizers, dispersion agents, and fillers to achieve good distribution, or is used as a masterbatch. Its primary uses are for tire compounds and, in particular, for adhesive compounds. The insoluble sulfur form is unstable. It is converted slowly at room temperature and rapidly at elevated temperature into the common soluble form. Insoluble sulfur must therefore be stored in a cool place and kept away from alkaline material. On incorporation, the temperature must not rise too far (maximum 120 °C). The use of insoluble sulfur instead of normal vulcanization sulfur does not influence vulcanization kinetics and the properties of vulcanizates [18].

To achieve uniform distribution in latex compounds and avoid sedimentation, the use of *colloidal sulfur* is necessary. Local overcure, which occurs readily in the environment of coarser sulfur particles and impairs the aging properties of vulcanizates, is avoided as a result of the fineness of the colloidal sulfur.

Rubber can be cross-linked with *selenium* and *tellurium*, but these elements are less active. They have no practical importance for reasons of both economics and, particularly, toxicity.

Sulfur Donors. Apart from elemental sulfur, organic sulfur compounds, which liberate sulfur only at elevated temperature, can be used for vulcanization. Sulfur donors are used mainly in combination with accelerators for the production of heat-resistant articles. Products used in practice are dimorpholyl disulfide (dithioldimorpholine DTDM, **1**), 2-morpholinodithiobenzothiazole (MBSS, **2**), caprolactam disulfide (DTDC, **3**), dipentamethylenethiuram tetrasulfide (DPTT, **4**), and isopropylxanthic tetrasulfide (**5**) [19, 20].

Thioplastics (i.e., thiokol rubbers) can also be considered sulfur donors because they can be used instead of sulfur for the vulcanization of rubber. Vulcanization with thiurams, which achieve cross-linking without actually liberating sulfur, is described in Section 2.5. The combination of sulfur donors with thiurams gives particularly aging-resistant vulcanizates with low compression set.

2.3. Vulcanization Accelerators

Sulfur is a sluggish cross-linking agent. Without the addition of accelerators and activators a reaction time of 5 h at 140 °C is required for cross-linking NR. In addition, although a sulfur dosage of 8 % is used, unsatisfactory cross-link densities, toughness, and aging properties are achieved. The vulcanization-accelerating effects of litharge, magnesium oxide, calcium hydroxide, and antimony sulfide were recognized soon after the discovery of sulfur vulcanization [21]. Since the introduction of organic accelerators, these inorganic ones have almost completely lost their importance. The history of accelerator development is very instructive for understanding accelerated sulfur cross-linking. In 1906, Oenslager in the United States recognized the activating effect of organic bases such as aniline on sulfur cross-linking [22]. For toxicological reasons, aniline was later replaced by thiocarbanilide (diphenylthiourea), the reaction product of aniline with carbon disulfide.

Since synthetic rubber reacts even more sluggishly than natural rubber, it cannot be vulcanized by using sulfur alone. Within the framework of synthetic rubber development, more active cross-linking systems were necessary. In 1910, Hoffmann and Gottlob discovered that ammonium dithiocarbamates – formed from aliphatic

and aromatic amines with carbon disulfide – aldehyde – amine condensation products, and guanidines were efficient vulcanization accelerators [23]. In experiments on the control of vulcanization kinetics, particularly the onset of reaction, dithiocarbamate derivatives were investigated, and zinc dithiocarbamate [24] and thiurams [25] were discovered (1919 – 1920). At about the same time, zinc oxide and stearic acid were found to be effective activators of accelerated sulfur cross-linking [26, 27]. Both compounds are still included in every sulfur cross-linking system. With organic accelerators and activators a significantly lower sulfur level could be used, which improved the aging properties of the vulcanizate. In 1921, mercaptobenzothiazole was discovered independently by Bedford and Sebrell at Goodyear Tire & Rubber [28] and by Bruni and Romani at Pirelli [29]. The onset of cure could be delayed significantly by derivatives of mercaptobenzothiazole. This finally led to the discovery of sulfenamides based on mercaptobenzothiazole at Bayer in 1931. These sulfenamides are the largest class of accelerators in terms of quantity and value [30].

The importance of organic vulcanization accelerators is based on the following factors: They greatly increase the rate of the cross-linking reaction with sulfur, which allows vulcanization time to be shortened to an economically justifiable level. Use of vulcanization accelerators also permits vulcanization at relatively low temperature and thus avoids heat damage to the rubber and improves aging resistance. Stepwise dosage and a combination of different accelerators enable the scorch and complete cure to be regulated, which are extremely important practical goals. Furthermore, the quantity of sulfur necessary for achieving optimal vulcanization properties is decreased, since the sulfur is used more efficiently for the formation of cross-links, and less is lost in undesirable side reactions. This leads to a considerable improvement in the aging resistance of rubber articles. Another important result of lower sulfur dosage is flattening of the vulcanization isotherm (plateau effect), which reduces the danger of overcure and impairment of vulcanizate properties.

Classification of Organic Accelerators. The list of commercially available accelerators for sulfur cross-linking systems currently consists of about 80 different substances, and the number of compounds that are capable of acceleration is even larger. Table 1 gives a summary of the most important accelerators grouped according to their chemical constitution, together with their international abbreviations.

Important accelerator producers and the trade names of their products are given below:

Akzo	Perkacit
Atochem	Ekaland
Bayer	Vulkacit
Chemetall	Naftocit
Goodrich	Good Rite
Kawaguchi	Accel
Kumho	Kumac
Monsanto	Santocure
Ouchi	Noceler
Robinson Brothers	Robac
Sanshin	Sanceller
Sumitomo Chemicals	Soxinol
Uniroyal	Delac

Figure 3 shows a comparison of the most important accelerators in which the normalized cure time achievable with them is plotted against the normalized scorch time (a measure of the resistance to cure onset) for natural rubber tread compounds. Individual members of each accelerator group naturally differ in their vulcanization behavior and can be classified further within ranges of cure times achievable.

Figure 3. Comparison of accelerators (equimolar amounts) in tread compounds

With skillful choice of an accelerator or a combination of accelerators, almost all desired processing and cross-linking characteristics, as well as vulcanizate properties, can be obtained. Typical sulfur cross-linking systems for carbon-

black-filled rubbers such as NR, SBR, NBR, butyl rubber (IIR), and ethylene – propene – diene copolymers (EPDM) are shown in Table 2. These conventional vulcanization systems (CV systems) differ in their sulfur content and in the nature and dosage of the accelerator, depending on the substrate. When starting from the basic formulations, special requirements can be fulfilled by variation of the sulfur – accelerator ratio and by combination of different accelerators.

Table 2. Typical vulcanization systems for carbon-black-filled elastomers

ZDBC, phr					1.5

Mechanism of Accelerated Sulfur Cross-Linking. The large number of possible factors affecting sulfur cross-linking can be better understood if the molecular course of cross-link formation is considered in more detail. The mechanism of accelerated sulfur cross-linking is, however, extremely complex and consists of many competing reactions. Most studies of the cross-linking of natural rubber by sulfur have been conducted by Malaysian Rubber Producer Research Association (MRPRA) in London, particularly from 1950 – 1980 [31]. Figure 4 summarizes the mechanism of accelerated sulfur cross-linking. The accelerator molecule (here exemplified by sulfenamide accelerators) reacts with the activators zinc oxide and stearic acid to give an amine-coordinated accelerator – zinc complex (A), which then reacts with sulfur to give a sulfur – accelerator complex (B). The exact composition of this complex is unknown; even whether or not it contains zinc is not known for certain. This sulfur – accelerator complex reacts with the rubber polymer, prefer-

Figure 4. Mechanism of accelerated sulfur cross-linking in natural rubber

ably in the allyl position, and forms a polymer-bound accelerator – polysulfane as the main intermediate (C). The latter reacts with a second rubber chain to form a polysulfidic cross-link only if zinc – accelerator complexes are present (D). However, zinc – accelerator complexes also catalyze the desulfurization of polysulfanes with the reformation of accelerator complexes having high sulfur content, and finally monosulfidic cross-links (F). The sulfur-rich accelerator complexes formed by sulfur extrusion can produce additional cross-links by reaction with the rubber chain. The polymer-bound accelerator – polysulfane can undergo purely thermal elimination reactions as side reactions, which lead to chain modification with the formation of diene and triene structures (G). A second side reaction is the formation of monsulfide bridges (E). The thermal decomposition of polysulfidic cross-links can lead to sulfur ring formation, a process that is associated with a decrease in the cross-link density (modulus reversion, H).

The balance of competing reactions determines the number and structure of cross-links. It depends on the sulfur – accelerator ratio, the structure of the zinc – accelerator complex, the cure temperature, and cure time. Sometimes these sulfur rearrangement reactions continue under service conditions. A high sulfur – accelerator ratio (conventional vulcanization system) favors polysulfidic cross-links, since only a small quantity of the zinc – accelerator complex is available for degradation of the polysulfides. With low sulfur – accelerator ratios (efficient vulcanization, EV system), many monosulfidic cross-links are formed because of a high concentration of the zinc complex.

2.3.1. Classes of Accelerators

Sulfenamides. Sulfenamides are the largest class of organic vulcanization accelerators in terms of quantity and value. They are produced by reaction of 2-mercaptobenzothiazole with

primary and secondary amines under oxidative conditions.

Compared with the accelerators mercaptobenzothiazole (MBT) and dibenzothiazyl disulfide (MBTS, see page 9), the sulfenamides (**6**) result in an extremely delayed onset of cure (longer scorch times) and thus greater processing safety. The thermal stability of sulfenamides varies depending on the nature of the substituents on nitrogen. This, in turn, varies the delay in cure onset. Processing safety increases from *N*-cyclohexyl-2-benzothiazylsulfenamide (CBS) to *N*-*tert*-butyl-2-benzothiazylsulfenamide (TBBS), then 2-morpholinothiobenzothiazole (MBS), and is greatest for *N*,*N*-dicyclo-2-benzothiazylsulfenamide (DCBS).

6

CBS: $R^1 = H$, R^2 = Cyclohexyl
TBBS: $R^1 = H$, R^2 = *tert*-Butyl
MBS: $R^1 + R^2 = -CH_2-CH_2-O-CH_2-CH_2-$
DCBS: $R^1 = R^2$ = Cyclohexyl

During vulcanization, sulfenamides are thermally cleaved to give a 2-mercaptobenzothiazyl compound and an amine. The latter acts as a strong secondary accelerator for the former, so that vulcanization proceeds very rapidly after the delayed start. The vulcanization behavior therefore corresponds to that with base-activated thiazole accelerators, except that the sulfenamides have a longer flow period. The vulcanization curves of compounds with sulfenamides thus approach the ideal curves for molded articles (i.e., long flow time and rapid complete vulcanization). The vulcanization rate can be increased by the addition of secondary accelerators, particularly thiurams, and the onset of cure can be delayed by retarders.

Sulfenamides are *used* in the production of tires, conveyor belts, and technical rubber goods that are vulcanized in heated presses. These accelerators are not suitable for hot-air vulcanization. Sulfenamides are decomposed rapidly by hot steam and slowly by moisture; therefore, steam vulcanization starts rapidly with sulfenamides. They are thus also used in combination with secondary accelerators for continuous vulcanization in steam (e.g., cable production).

The thiocarbamylsulfenamides **7** and **8** [32, 33] give vulcanizates with good resistance to reversion.

7

8

The characteristics of vulcanization are broadly similar to those achieved with a combination of MBT-derived sulfenamides and dithiocarbamates. The advantage of thiocarbamylsulfenamides compared to these combinations is the clearly more favorable resistance to cure onset. Thiocarbamylsulfenamides show a strong synergistic effect in combination with other accelerators. Their main uses are in retread compounds for tires and in heat-stable products with low compression set (e.g., engine mountings).

Thiazoles. The thiazoles considered here (**9** – **11**) are derivatives of 2-mercaptobenzothiazole and represent an important class of accelerators.

9

10

11

2-Mercaptobenzothiazole (MBT),**9** and dibenzothiazyl disulfide (MBTS)**10** are all-purpose accelerators for almost all rubber. With MBT, vulcanization starts rapidly, and with MBTS it is somewhat delayed. The zinc salt of 2-mercaptobenzothiazole (ZMBT)**11** is used mainly in latex compounds. These three "mercapto accelerators" give an average vulcanization rate, a broad plateau, relatively high processing safety, and very good resistance to vulcanizate aging. They are used either alone or, preferably, in combination with other accel-

erators, particularly guanidines, thiurams, and dithiocarbamates. Combinations of mercapto accelerators and basic accelerators, such as *N*,*N*′-diphenylguanidine (DPG), act synergistically. Combinations of, for example, MBTS – DPG or MBT – hexamethylenetetramine are important in industry because of their enhanced vulcanization rate and their high degree of cross-linking. Premixed combinations of this type are available commercially.

2-Mercaptobenzothiazole, dibenzothiazyl disulfide, and their combinations with other accelerators are *used* in the production of technical rubber goods, such as conveyor belts, V-belts, seals, footwear, and rubber threads. The vulcanizates have a bitter taste, so they are not suitable for products that come in contact with foods.

Thiurams. The main thiuram vulcanization accelerators are **12** – **17**.

The most important product in this range is tetramethylthiuram disulfide (TMTD, **12**). Tetrabenzylthiuram disulfide (**17**) [34, 35] an alternative to other thiurams in many applications because the latter can form carcinogenic nitrosamines (see Section 2.3.2) under vulcanization conditions.

The thiuram accelerators produce faster onset of cure and more complete cure than thiazoles. They are therefore employed for more rapid vulcanizations and, in particular, as secondary accelerators for the mercapto and sulfenamide accelerators. Tetramethylthiuram monosulfide (TMTM, **13**) gives a better resistance to cure onset than the disulfide (TMTD).

At higher dosages (2 – 5 %), vulcanization can be carried out with thiuram di- and polysulfides with or without small quantities of sulfur (efficient vulcanization, EV). The vulcanizates formed are characterized by good heat resistance and low compression set, and metals (copper, silver) coming in contact with the vulcanizates are not darkened by sulfide formation. Thiuram vulcanization is used for the production of heat-resistant articles (e.g., seals from NBR). Thiuram accelerators are often used as components of vulcanization systems for ethylene – propylene terpolymers (EPDM rubbers).

Dithiocarbamates. Dithiocarbamates (**18**) have the strongest vulcanization accelerating action (ultraaccelerators).

18

The compounds employed most frequently are zinc *N*-diethyldithiocarbamate (ZDEC), zinc *N*-dimethyldithiocarbamate (ZDMC), and zinc *N*-dibutyldithiocarbamate (ZDBC). To a lesser extent, other zinc, selenium, tellurium, lead, copper, or alkaline-earth salts of dithiocarbamic acids are used. Besides these metal salts, dialkyl- and alkylcycloalkylamine dithiocarbamates (e.g., the piperidine salt of pentamethylenedithiocarbamic acid) are used. Zinc dibenzyldithiocarbamate is gaining importance as an alternative to nitrosamine-forming dithiocarbamates (see Section 2.3.2) [36]. Dithiocarb-

12

13

14

15

16

17

amates are added to compounds, that are to be vulcanized at low temperature in the shortest possible time. Examples are dipped articles, rubberized fabrics, self-vulcanizing solutions (sometimes in combination with bases), and latex articles. The rapidly starting vulcanization requires special attention during processing. The vulcanization rate is highest with ammonium salts, while zinc salts exhibit greater processing safety. Besides use in latices, dithiocarbamates are the preferred agents for EPDM cross-linking and are used as activators for thiazole and sulfenamide cross-linking.

Guanidines. Guanidine accelerators, such as *N*,*N*′-diphenylguanidine (DPG), *N*,*N*′-di-*o*-tolylguanidine (DOTG), and *o*-tolylbiguanide (OTBG) are not important as individual accelerators because their accelerating action is low. Without addition of other accelerators, they are used only for the vulcanization of voluminous articles. However, they are important secondary accelerators for thiazoles because such combinations result in faster vulcanization and higher cross-link densities than the individual substances.

Guanidines can be used as activators for sulfenamides to increase reaction rate. Combinations of guanidine and thiazole accelerators are used in compounds with silica fillers, because basic guanidines counteract the delay in cure onset produced by silicic acid. *o*-Tolylbiguanide is an important accelerator for rubber used in contact with foods.

Thioureas. Ethylenethiourea (ETU, 2-mercaptoimidazoline) and diethylenethiourea (DETU) are used mainly as accelerators for the vulcanization of polychloroprene and epichlorohydrin. With zinc oxide they give high cross-link densities. DETU gives a rapid onset of cure; ETU, a somewhat slower one. Thiazoles, such as MBTS, are used as retarders. In EPDM, thioureas are highly activating, particularly in compounds containing calcium oxide. Because of the teratogenic effects of ETU [37], the use of thioureas is decreasing, and they are supplied preferably as polymer-bound granulates,which effectively hinder exposure to and inhalation of thiourea dust.

Other Accelerators for Sulfur Vulcanization.

Aldehyde – Amine Condensation Products. Aldehyde – amine condensation products differ greatly in their accelerating effects. Hexamethylenetetramine (Hexa) is used as an inexpensive, basic secondary accelerator in combination with mercapto accelerators, particularly in light compounds. Its action is similar to, but slower than, that of diphenylguanidine.

Tricrotonylidenetetramine is a special accelerator for the vulcanization of hard rubber compounds, but it vulcanizes relatively slowly. An accelerator that acts more rapidly is the condensation product of butyraldehyde with aniline. This product gives vulcanizates with high elasticity and is used for the production of rubber buffers.

Amines. Amines, such as cyclohexylethylamine, have a strong secondary accelerating effect on dithiocarbamates. For self-vulcanizing adhesive solutions, zinc *N*-ethylphenyldithiocarbamate is used in combination with cyclohexylethylamine. Amines, such as di- or triethanolamines and polyethylene – polyamines, are used as activators for active silica fillers.

Dithiophosphates. The most important dithiophosphate accelerator is zinc dibutyldithiophosphate (**19**).

19

Copper diisopropyldithiophosphate and zinc aminedithiophosphates are used to a lesser extent, mainly in cross-linking of EPDM. Here they are used in combination with thiazoles, sulfenamides, and zinc dibenzyldithiocarbamate (ZBEC), which are almost free of nitrosamines (see page 10).

Xanthate Accelerators. Xanthates, such as sodium isopropyl-, zinc isopropyl-, and zinc dibutylxanthate act similar to dithiocarbamates; however, they have not achieved the same importance. They are sometimes used for the production of self-vulcanizing adhesive solutions and with latices for the production of rubber foams.

Triazine Accelerators [38]. Triazine accelerators are similar in structure and activity to thi-

azoles. In addition to its accelerating action the tetrasulfide (**20**) also acts as a sulfur donor.

$x = 2,4$

20

Compared with thiazole accelerators, triazines give rise to higher cross-link densities and better stability to reversion of the vulcanizates. Because of their high price and limited availabilty, triazines remain specialized products for use in a few applications.

2.3.2. Toxicology and Ecology of Organic Vulcanization Accelerators

The acute biological (oral and dermal toxicity; irritation of the skin and eyes) and environmentally damaging properties of cross-linking agents have been thoroughly investigated and are well known. They are summarized in the safety data sheets of producers and are shown on packaging labels. Most cross-linking agents are harmless on acute exposure [39]. However, besides the toxicity of the chemicals themselves, the hazards of their decomposition products, which can be present in vapors emitted during vulcanization, must be considered. In the rubber industry, nitrosamines are particularly important. In experiments with animals, most nitrosamines have been shown to be carcinogenic [40]. Stable nitrosamines are formed by nitrosation of secondary amines, which are liberated from accelerators and sulfur donors, and sometimes from short stoppers with the appropriate structure. Fillers (with absorbed NO_x) or production processes (salt baths) can have nitrosating potential. The role of NO_x, ubiquitous in air, is still disputed [41].

In the second amendment of the Chemikaliengesetz (1990), exposure limits with TRK values of 1 and 2.5 µg/m^3 are stipulated for 12 of the nitrosamines frequently occurring in industry. Similar regulations in the EC and the United States are anticipated. Since secondary amines are a necessary prerequisite for the formation of stable nitrosamines, the latter can be prevented by the avoidance of secondary amine sources by product substitution. In the case of sulfenamides this is achieved by the use of compounds based on *primary amines*, such as CBS and TBBS, sometimes in combination with vulcanization retarders. If the use of *secondary amines* is unavoidable, then amines whose nitrosamines have not been found to be carcinogenic in animal experiments (so-called safe amines) should be used. Dicyclohexylamine and dibenzylamine are the most important examples of these. Accelerators based on these amines are the sulfenamide DCBS, the thiuram tetrabenzylthiuram disulfide (TBzTD), and the dithiocarbamate ZBEC. Dicaprolactam disulfide is a sulfur donor that does not form nitrosamines. Since most of the nitrosamines in the rubber matrix are formed during vulcanization, the addition of NO_x scavengers results in a reduction in nitrosamine content. Normal compounding ingredients, such as phenolic antioxidants, amines, and metal oxides, can have scavenging effects. Additives such as α-tocopherol, ascorbic palmitate [42], and urea derivatives [43] are also used as scavengers. Their action depends strongly on the formulation and process used, and requires testing of the targeted nitrosamine reduction in individual cases. Scavengers can contribute to maintaining TRK values and thus represent a short-term solution to nitrosamine minimization. The complete avoidance of nitrosamines is possible only through product substitution.

2.3.3. Delivery Forms of Vulcanization Accelerators [44]

The homogeneous distribution of cross-linking ingredients is a prerequisite for good vulcanizate properties. The level of dispersion depends on factors such as the compound viscosity, shear gradient during compounding, solubility, melting point, and particle size. From the view point of the production engineer, the main requirements of the delivery form are automatic dosability, and suitability for storage in large containers and silos. Industrial hygiene requires that the product be dust free. The wide variety of forms supplied corresponds to this broad catalogue of requirements and includes powders, microgranulates (from spray drying), extrusion granulates with 0 – 5 % oil, pastes, wax granulates (> 5 % oil, wax), and predispersed

polymer-bound granulates. The form supplied must be suited to the requirements in an individual case.

2.4. Accelerator Activators

To develop the full activity of organic vulcanization accelerators, they must always be used in combination with inorganic and organic activators. The addition of *zinc oxide* to rubber compounds containing sulfur and accelerators considerably increases cross-link density. For the general-purpose rubbers NR and SBR, increasing zinc oxide dosage up ca. 5 phr leads to high tensile strength and stress values. Higher dosages have no further effect on these properties.

The effects of *cadmium* and *bismuth oxides* are similar to those of zinc oxide. However, they are not used because of economic and ecological reasons. *Magnesium* and *calcium oxides* are less suitable since they produce much lower cross-link densities. The lead oxides PbO and Pb_3O_4 are used as activators when vulcanizates with particularly low swelling in water are required.

The rubber – sulfur – accelerator – zinc oxide system is further activated by fatty acids. Stearic acid or zinc stearate is generally used. Besides activation, fatty acids and their salts improve processibility and filler distribution, which are important for vulcanizate properties. The use of special zinc salts besides ZnO can lead to an increase in cross-link density and an improvement in reversion behavior [45]. Zinc diamminediisocyanate has been introduced for cross-linking of EPDM [46]. Through activation of cross-linking kinetics and improvement of compression set zinc diamminediisocyanate in combination with MBT, dibutyl dithiophosphate, and ZBEC offers a new EPDM cross-linking system that forms no carcinogenic nitrosamines but nevertheless offers the combination of properties provided by classical accelerator systems.

2.5. Sulfur-Free Cross-Linking Agents

2.5.1. Peroxides (Organic Peroxides and Peroxycarboxylic Acids) [47]

The cross-linking of rubber with peroxides (dibenzoyl peroxide) was first carried out by Ostromislensky in Russia in 1915 [48]. However, industrial interest in this form of cross-linking developed only with the discovery of di-*tert*-butyl peroxide and dicumyl peroxide (in ca. 1950) for the cross-linking of polyethylene, and with the introduction of saturated synthetic rubber grades, such as silicone rubber (Q) and ethylene – propylene – diene copolymers (EPM, EPDM). Peroxides are the most important cross-linking agents for rubber containing few or no double bonds in the chain. Examples are silicone rubber, EPDM, ethylene – vinyl acetate copolymers (EVM), and hydrogenated acrylonitrile – butadiene copolymers (HNBR). Since rubbers containing double bonds, such as NR, SBR, BR, NBR, and chloroprene rubber (CR), generally require the addition of large quantities of antidegradants, cross-linking with peroxide is used only in exceptional cases, for example, to achieve particular heat resistance or low compression set.

For the cross-linking of high molar mass polymers, only peroxides that are sufficiently stable under processing conditions are suitable. The decomposition temperature of peroxides depends on their structure. The half-life of decomposition determines the resistance of cure onset and the cross-linking rate at a given temperature. The addition of activators, such as zinc oxide and stearic acid, is not necessary. The most important cross-linking peroxides are acyl peroxides, perketals, and alkyl or aralkyl peroxides. Acyl peroxides and perketals generally have lower decomposition temperatures than alkyl peroxides.

Acyl peroxide

21

Perketal

22

Alkyl- and aralkyl peroxides

23

24

25

Bis(2,4-dichlorobenzoyl) peroxide (**21**) is used mainly for cross-linking of silicone rubber. The perketal *1,1-di(tert-butylperoxy-3,3,5-trimethylcyclohexane* (**22**) results in very rapid cross-linking even at moderate temperature. *2,5-(tert-Butylperoxy)-2,5-dimethylhexane* (**23**) has good processing safety and is used mainly to cross-link EPDM and silicone rubber.

The most important products in terms of quantity are *dicumyl peroxide* (**24**) (for polyethylene cross-linking in cable applications) and *bis(tert-butylperoxyisopropyl)benzene* (**25**) (for cross-linking a wide range of rubber types).

For cross-linking elastomers the preferred peroxides are those that form the following radicals:

Cumyloxy Phenyl *tert*-Butyloxy Methyl

These radicals are very reactive and can abstract hydrogen atoms from rubber molecules. The polymer radicals thus formed produce a carbon – carbon cross-link upon recombination (Fig. 5).

Figure 5. Mechanism of peroxide cross-linking

Besides radical recombination the polymer radical can also be stabilized by chain cleavage. This behavior is especially pronounced with polymers having tertiary carbon atoms, for example, butyl rubber (IIR), epichlorohydrin rubber (ECO), and thermoplastics such as polypropylene. Thus, peroxides are not suitable for cross-linking these polymers.

The kinetics of peroxide cross-linking depend primarily on the structure of the peroxide and the vulcanization temperature, and less on the structure of the polymer. Therefore, blends of polymers that possess widely differing reactivities with regard to sulfur cross-linking can be covulcanized very successfully. Examples are NR – EPDM and NBR – EPDM blends for hosing, NBR – EVM blends for seals with improved light and good oil resistance, and PE – EPDM blends with improved extrusion behavior.

Interactions of peroxide cross-linking agents with various formulation ingredients must be reckoned with. Refined mineral oils (e.g., paraffinic and, under certain conditions, naphthenic oils) are suitable extenders. Highly aromatic oils cannot be used. Synthetic plasticizers generally do not have any negative effects.

Acidic fillers favor the heterolytic decomposition of peroxides, with the formation of ionic

intermediates that do not result in cross-linking. Silica, silicates, kaolin, and talc, which tend to absorb cross-linking agents, should be combined with activators such as diphenylguanidines or polyglycols.

The use of antioxidants is problematic because they are intended to react immediately with free radicals. Small dosages of oligomerized trimethyldihydroquinoline (TMQ), 4,4′-thiobis-6-*tert*-butyl-*m*- cresol, and methylmercaptobenzimidazole (MMBI) allow peroxide vulcanization to proceed without too significant a decrease in cross-link density. Within certain limits the resistance to cure onset [e.g., with butylated hydroxytoluene (BHT)] can be controlled by antioxidants.

Peroxide cross-linking of *polymers that tend to undergo chain cleavage* can often be achieved by using coagents (polyfunctional polymerizable compounds, such as ally and methacrylate compounds) [48]. Coagents significantly increase the cross-link density and improve vulcanizate properties (such as compression set or heat resistance) because they are incorporated into the vulcanizate as cross-links. Common coagents are diallyl terephthalate (DATP), ethylene glycol dimethacrylate (EDMA), trimethylolpropane trimethacrylate (TRIM), triallyl cyanurate (TAC), triallyl isocyanurate (TAIC), *N*,*N*′-*m*-phenylenedimaleinimide, and 1,2- *cis*-polybutadiene.

The choice of the best coagent depends on the compound and the technical requirements. Peroxide vulcanization is carried out mainly in processes such as during mold curing,injection molding, transfer molding, and oxygen-free steam vulcanization, and in salt baths. Hot-air and ultra high-frequency processes are used only in exceptional cases (e.g., silicone cross-linking with 2,4-dichlorodibenzoyl peroxide) since these processes generally produce sticky,adhesive surfaces.

Peroxide- cross-linked vulcanizates generally have lower tear resistance and tensile strength than sulfur- cross-linked elastomers, but excellent heat resistance and low compression set, particularly at high temperature [49].

Forms of Peroxides Supplied. Depending on their thermal stability, peroxides are available commercially in the technically pure form; desensitized on carriers such as chalk, kaolin, or silica; or mixed with polymers such as EPM – EDPM, EVA, or PE (active substance content of the formulation, usually 40 %). The forms of the active substances and mixtures supplied include liquids, pastes, powders, granules, and masterbatch sheets or granules.

Peroxide Producers. Important producers of peroxides are listed below, together with the trade names of the corresponding products:

Akzo	Trigonox, Perkadox, Lucidol, Cadox
Atochem	Luperox, Luperco, Alperox
Herkules	Di-Cup, Vul-Cup
Pennwalt	Luperox, Lupersol
Peroxid Chemie	Interox

Toxicity. Most peroxides used for cross-linking are either slightly toxic or nontoxic. Being oxidizing agents, they cause some skin irritation. Decomposition products of certain peroxides can cause unpleasant odors under vulcanization conditions, for example, the penetrating odor of acetophenone from dicumyl peroxide. Other peroxides are currently available whose decomposition products have considerably less powerful odors. New types of peroxides with groups capable of polymerization permit the incorporation of cleavage products into the polymer (e.g., *tert*-butylperoxy isopropylmethylstyrene initiator D 120) [50].

2.5.2. Quinone Dioxime

p-Benzoquinone dioxime and its dibenzoyl derivative are used mainly for cross-linking butyl rubber in the presence of oxidizing agents, such as lead oxides, because the resulting vulcanizate is especially heat and steam resistant. One area of use is in bladders for tire presses.

2.5.3. Polymethylolphenol Resins

Vulcanization using imcompletely reacted polymethylol resins is also limited mainly to the cross-linking of butyl rubber. In the course of vulcanization the resins are incorporated into the polymer molecules as parts of the cross-links. As in the case of quinone dioxime cross-linking agents, the vulcanizates have good heat

and steam resistance. Compounds such as tin(II) chloride are used to activate the resins. Certain halogenated resins can react without these activators. Since about 1989, resin cross-linking has also been used in the production of thermoplastic polyolefins (TPO) (→ Thermoplastic Elastomers).

2.5.4. Other Cross-Linking Agents

Zinc and magnesium oxides can be used to cross-link rubbers that contain either halogens or carboxyl groups. The mechanisms of reaction of the two groups are quite different.

Rubber Containing Carboxyl Groups. In the case of carboxyl- containing rubbers – of which carboxylated SBR and NBR are economically significant – a pure salt cross-linking occurs. Since salt cross-linking is extremely problematic because of the rapid onset of cure, the processing and cross-linking of carboxyl- containing polymers is generally limited to latex technology. In principle, all di- or polyvalent cations can be used for this type of cross-linking. Zinc oxide is the most commonly used.

Halogen-Containing Rubber. The cross-linking of halogen- containing rubber by metal oxides follows quite a different mechanism. With *unsaturated polymers* such as polychloroprene, and chlorinated or brominated butyl rubber, cross-linking starts with the abstraction of an allylic halogen which is initiated by metal oxides. Both zinc and magnesium oxides can be used for this purpose. With polychloroprene, a combination of both oxides is used to achieve optimum stability on storage and resistance to cure onset. With *sulfur-modified grades*, no accelerators are used, whereas other polychloroprene grades require the addition of organic accelerators for optimal vulcanization. In the cross-linking of halogenated butyl rubber, zinc oxide is used alone or, to achieve particular properties, in combination with accelerators such as MBTS or TMTD. 3-Methylthiazolidine-2-thione is a possible alternative to ETU in polychloroprene cross-linking [51].

If used with *saturated halogen- containing polymers*, zinc oxide catalyzes the formation of hydrochloric acid. For this reason, zinc oxide is not used with chlorinated or chlorosulfonated polyethylene; instead, magnesium oxide is used in combination with special accelerators such as 2,5-dimercaptothiadiazole.

Special rubbers, which require cross-linking agents specifically suited to the type of polymer (e.g., fluoro- or acrylate rubbers), are discussed in → Rubber, 3. Synthetic in the sections dealing with the particular polymers.

2.5.5. Radiation Cross-Linking [52] (see also → Radiation Chemistry, Chap. 1.3.2.2)

Rubber can also be cross-linked without the addition of cross-linking agents, by high-energy radiation such as gamma rays (for example, from cobalt sources) or high-energy electrons (from electron accelerators), with the formation of carbon – carbon bonds. Very compact electron accelerators are now available, which can be incorporated into on-line production processes [53]. An example is the radiation cross-linking of inner liners in tire production, where dimensional stability and building tack are both increased. This allows economy of materials and construction, with a reduced number of building components. The main uses of electron radiation cross-linking are for wire insulation and coatings. A limitation in the use of radiation cross-linking is the relatively short penetration depth. An advantage is the absence of cross-linking agents and their reaction products; therefore, radiation cross-linking is used for the production of disposable medical articles.

2.6. Vulcanization Retarders [54, 55]

The fine adjustment of resistance to cure onset frequently requires the addition of retarders, despite the large number of different accelerators available, particularly when high processing or vulcanization temperatures are used. Acidic substances generally retard the vulcanization of general-purpose diene rubbers. Organic acids and anhydrides, such as benzoic acid, salicylic acid, or phthalic anhydride, are used as vulcanization retarders. Fatty acids and their salts, such as stearic and oleic acids, zinc stearate, and zinc laurate, can also delay the onset of cure. Sulfenic acid derivatives of acidic nitrogen compounds are considerably more effective.

26

27

The commercially most important and widely used product is cyclohexylthiophthalimide (CTP) (**26**), which exhibits the greatest efficiency with sulfenamide and thiazole accelerators, even at extremely low dosage (0.05 – 0.3 phr). The addition of CTP results in a parallel shift in the vulcanization isotherm along the time axis, while other vulcanization properties are hardly affected. Trichloromethylthiosulfanilide (**27**) is a special retarder from the same class of substances, which is used preferably in combination with thiazole accelerators. Thiurams are barely affected by these types of S – N compounds, but the resistance to onset of cure can be improved by addition of thiazole accelerators and, in particular, sulfenamides.

3. Antidegradants

3.1. Appearance of Aging and Fatigue [4, 56 – 61]

The aging of a material is defined as changes in its properties with time as a result of external influences or use. This does not include changes due to wear and tear (e.g., mechanical damage or abrasion). Aging can manifest itself in vulcanizates in many different ways. The observed changes include:

1) Hardening, embrittlement
2) Softening, becoming sticky
3) Loss of toughness
4) Loss of elastic properties
5) Cracking
6) Changes in the nature of the surface (frosting, crazing, loss of color, gloss, and feel)

In addition, other changes (e.g., in electrical properties, development of odors) can occur.

As seen from this list, the changes can affect either the entire rubber article or only the surface. Aging processes that affect the whole article (bulk processes) are:

1) Aging due to oxygen at low and high temperature (aging in the narrow sense)
2) Aging due to rubber poisons
3) Aging due to heat
4) Aging due to hot water or steam
5) Aging in hot media

Aging processes on the surface include:

1) Dynamic cracking due to oxygen
2) Static and dynamic cracking due to ozone
3) Crazing
4) Frosting

Aging due to Oxygen at Low and High Temperature. The determining factors in aging due to oxygen and heat are the oxygen in the ambient air and the temperature. Even at room temperature, oxygen tends to promote aging processes, which naturally occur more rapidly with increasing temperature. Aging due to oxygen involves continuous absorption of oxygen (initiated by a chain reaction). Atmospheric oxygen is partially bonded to the vulcanizate and partially liberated in the form of carbon monoxide, water, and low molar mass oxidation products. Reactions involving oxygen proceed by a chain mechanism. Basic experiments on autoxidation (i.e., self-accelerating oxidation) involving kinetic investigations of low molar mass saturated hydrocarbons in the liquid phase were carried out by Bolland and Gee [62, 63].

Initiation reaction

$RH \rightarrow R\cdot$ (1)

Chain propagation

$R\cdot + O_2 \rightarrow ROO\cdot$ (2)

$ROO\cdot + RH \rightarrow ROOH + R\cdot$ (3)

Chain branching

$ROOH \rightarrow RO\cdot + HO\cdot$ (4)

$RO\cdot + RH \rightarrow ROH + R\cdot$ (5)

$HO\cdot + RH \rightarrow H_2O + R\cdot$ (6)

Chain termination

$2\,R \rightarrow R{-}R$ (7)

$R\cdot + ROO \rightarrow ROOR$ (8)

$2\,ROO\cdot \rightarrow ROOR + O_2$ (9)

Although the exact mechanism of the initiation reaction (1) is still unclear, the alkyl radical R· is generally assumed to be formed by absorption of energy in the form of heat or UV radiation or by reaction with traces of heavy metals. The actual chain carriers in the chain propagation reaction are alkyl radicals R· and peroxy radicals ROO·. The peroxy radicals are less reactive and

therefore quite selective. They preferably attack very reactive C – H bonds (those next to an aromatic nucleus or in the allyl position, tertiary C – H bonds, or C – H bonds adjacent to oxygen as in aldehydes or ethers). The chain branching step (4) requires high activation energy and is therefore the main reaction at high temperature. The radicals RO· and HO· formed in reaction (4) are capable of reacting with RH – like the peroxy radicals – and thus can also initiate new chain reactions (reactions 5 and 6); the rate of oxidation becomes markedly higher (kinetic chain branching). Chain termination can occur by recombination of radicals, which may however decompose again and initiate new radical chain reactions.

The sensitivity of high molar mass polymers to oxidation depends first on their content of double bonds and second on the groups (atoms) next to the double bonds. Polymers with a high double bond content, such as NR and BR, are therefore more sensitive to autoxidation than EPDM or EVM with their completely saturated main chains. Methyl substituents next to double bonds [NR, isoprene rubber (IR)] favor autoxidation, while the shielding effect of chlorine in polychloroprene gives rise to better resistance to aging. Tertiary carbon-atoms, which are readily converted into hydroperoxides, constitute weak points in the methyl-substituted products.

The oxygen absorbed can initiate the following reactions within the article depending on the type of rubber:

1) Cleavage of the polymer chain, whereby the vulcanizate network is weakened (degradation, softening)
2) Cross-linking, whereby the vulcanizate network density is increased (cyclization, hardening)
3) Chemical bonding of the oxygen (e.g., as hydroxyl or keto groups), without chain cleavage or formation of new cross-links

The relative extent of occurrence of these three competing reactions determines the amount of changes in the mechanical properties that occur during aging. The first two reactions result in large changes, whereas the third is comparatively harmless.

The aging behavior of natural rubber, synthetic isoprene, and butyl rubber can vary depending on the conditions chosen. In contrast, with vulcanizates based on SBR, BR, NBR, EPDM, CR, and many other synthetic rubber types, the second reaction (cross-linking) predominates from the beginning, so that hardening occurs. Because of this, an increase in modulus and a decrease in elongation at break are observed. On hot-air aging at 150 °C, butyl rubber exhibits considerable softening after 13 d (chain cleavage), whereas EPDM hardens. Completely oxidized natural rubber vulcanizates are generally hard, brittle, and thermoplastic. The decrease in the elongation at break is generally used to characterize the aging resistance of polymers. For natural rubber, the decrease in tensile strength is often also evaluated.

Aging resistance depends not only on the type of rubber and the antidegradants, but also the cross-linking system used. In sulfur vulcanization, aging resistance depends on the distribution of mono-, di-, and polysulfidic cross-links in the network. With an increasing proportion of mono- and disulfidic cross-links, aging resistance in the narrow sense (aging due to oxygen and heat) increases. Sulfenamides and, in particular, mercapto accelerators give vulcanizates with better aging resistance than those produced with dithiocarbamates. Vulcanizates produced with sulfur donors are more resistant to aging than those produced with sulfur itself. Thiuram vulcanization also gives good aging resistance. Factice and reclaimed rubber favorably affect resistance to aging as, in general, do high dosages of white fillers. Vulcanizates cross-linked without sulfur (using quinone dioxime, peroxides, or resins) have the greatest aging resistance.

Aging due to Rubber Poisons. The activation energy of the chain reactions in autoxidation is lowered by the catalytic action of heavy-metal ions. Uncontrolled acceleration of the oxidation is initiated at much lower temperature than in the absence of heavy-metal ions. This catalytic action is due to formation of radicals from the alkyl hydroperoxides (hydroperoxide decomposition) and to the formation of radicals in the initiation phase (see below). The most well known rubber poisons are iron [particularly Fe(II)], copper, manganese, cobalt, and nickel.

Initiation phase

$$Me^{2+} + RH \rightarrow Me^{+} + H^{+} + R\cdot$$

$$Me^{2+} + RH \longrightarrow Me^{+} + H^{+} + R^{\bullet}$$
$$Me^{+} \xrightarrow{(O_2)} Me^{2+}$$

Hydroperoxide decomposition

$$Me^{2+} + ROOH \rightarrow Me^{+} + H^{+} + ROO^{\bullet}$$
$$Me^{+} + ROOH \rightarrow Me^{2+} + OH^{-} + RO^{\bullet}$$

Natural rubber and polyisoprene are considerably more sensitive toward rubber poisons, particularly copper and manganese, than synthetic rubbers such as SBR, BR, and NBR. Polychloroprene is in an intermediate position with regard to sensitivity. The chemical form in which the heavy-metal ions are present is very important. The solubility of the metal compound in the rubber seems to play the major role. Thus, the soluble compounds copper stearate and oleate are powerful aging accelerators. After these, in order of decreasing reactivity, are copper sulfate and chloride, copper oxide, and metallic copper. Complexes such as copper phthalocyanine are virtually inactive and harmless, as is, for example, copper dimethyldithiocarbamate. The same applies to iron compounds, so that the iron oxide pigments and complexes (e.g., iron ethylenetetramine) commonly used in the rubber industry can be regarded as harmless. The accelerator system is also important for the sensitivity of vulcanizates toward rubber poisons. Vulcanizates produced with basic accelerators are more sensitive than those produced with acidic ones. In thiuram vulcanizates, copper compounds can even act as antioxidants or at least behave neutrally. Whether the poison enters the rubber during compounding (e.g., with the fillers) or from external contact (e.g., bare copper tubing, textiles containing copper dyes) does not make any difference in principle. As a rule of thumb, the content of rubber poisons should be <0.001 %.

Heat Aging. At temperatures of more than 100 °C even in the presence of oxygen, the heat factor is considered most important, and at this temperature heat aging occurs. The action of heat alone produces post- cross-linking, cyclization, or reversion. With NR and IR, *reversion* predominates after longer warming periods (i.e., thermal degradation occurs). This is sometimes known as overcure.

CR and EPDM are typical examples in which inter- or intramolecular cross-linking (hardening) continues at higher temperature. This *post- cross-linking* is caused by the vulcanization agent, as well as by reactive groups in the rubber itself. BR, SBR, and NBR also undergo hardening, but on strong overheating, softening begins. The term *cyclization* is not always unambiguous. Here, it should be understood as additional cross-linking of the vulcanizate. Cyclization can also be important in hot processing of raw synthetic rubber or its compounds (SBR, NBR) in the absence of cross-linking agents. In this case an increase in viscosity occurs.

Besides these reactions, *rearrangement of network bonds* can occur without changing their effective number. The physical effects observed are small.

Hot Water and Steam Aging. A special case of heat aging – the effect of steam or hot water on the vulcanizate – results in partial or total exclusion of air. In particular, rubber that is not sensitive to hydrolysis can be exposed in water or steam to higher temperature than in hot air. Silicone rubber, ethylene – vinyl acetate polymers, polyurethanes, and some other polymers with ether or ester bonds are, however, degraded quite rapidly. The C – O, C – N, and Si – O bonds are cleaved hydrolytically.

Aging in Hot Media is also a special case of heat aging. In addition to the heat effects already described, the simultaneous action of swelling and aggressive media must be considered. Besides the possible extraction of compounding ingredients such as plasticizers (changes in hardness, elongation at break, etc.) and antidegradants, the resistance of the polymer toward the medium concerned is important.

Dynamic Cracking under the Effect of Oxygen. If rubber is subjected to continuous changes in mechanical stress (e.g., periodically bend backwards and forwards), cracks gradually appear in the surface, which increase in size and can finally lead to complete breakage of the article. These cracks occur perpendicular to the direction of stress. Natural rubber forms these cracks relatively rapidly, but they then develop slowly. Crack formation occurs later in SBR and polybutadiene, but is followed by rapid growth. This is associated with lower tear resistance. Raising the temperature accelerates cracking, as does increasing the degree and frequency of de-

formation. Flex cracking or fatigue occurs particularly rapidly if the deformation cycle is not sinusoidal but shows leaps and bounds.

Even the fillers and the cross-linking system have an effect on the fatigue behavior of vulcanizates. Carbon black is more advantageous (i.e., it counteracts dynamic cracking to a certain extent) than inactive, white fillers. With the sulfur cross-linking system the ratio of mono-, di-, and polysulfidic cross-links plays a decisive role, because the latter are more fatigue resistant than the former.

Static and Dynamic Cracking due to Ozone. If vulcanizates in the statically elongated state or under dynamic load are exposed to weathering, cracks gradually appear perpendicular to the direction of elongation (tension). These cracks gradually increase in size and can also lead to breakage of the vulcanizate. This phenomenon is caused by the small quantity of ozone present in the atmosphere. Investigations have shown that the Criegee mechanism [64] of ozonolysis of olefins is also valid for rubber [65, 66] (see Fig. 6).

Figure 6. Ozonolysis of polymers

In a 1,3-dipolar cycloaddition the double bond is attacked by ozone. The unstable primary ozonide I decomposes simultaneously into a carbonyl compound II, and a carbonyl oxide III. In the unextended – not stressed state, more than 50 % of the cleaved fragments again undergo a 1,3-dipolar addition, this time to give the actual ozonide IV. In the extended state, these cleaved fragments are removed from the reaction cage and can, for example, react with neighboring molecular chains or other molecules. In molecular chains, which are arranged parallel to the direction of tension, this process leads to microscopically small cracks perpendicular to the direction of stress.

Without extension and stress no cracks are formed in the vulcanizate. A critical extension – which is <10 % for NR – must be exceeded. The number of cracks formed per unit area and time increases with increasing extension, but their length and depth decrease. An increase in temperature has the same effect as an increase in extension: the number of cracks increases, and their depth decreases. In accordance with the reaction mechanism the most highly unsaturated rubbers, such as NR, SBR, BR, IR, and NBR, are the most sensitive toward ozone cracking. CR is much more resistant, because of the shielding effect of the chlorine atom. Completely saturated elastomers naturally have the best ozone resistance.

Although it has been known for some time that light is not to be the major cause of this type of cracking, the expression "sun cracking" is persistently used. This is correct only in so far as high-energy radiation (UV light) produces ozone, whose effect is more pronounced in mountains than in low-lying land and is stronger in spring or summer than in winter. All types of electrical discharge (spark formation on electric motors or electric arcs) cause locally high ozone concentrations, as does gasoline exhaust.

Crazing. On prolonged exposure of light-colored vulcanizate to sun, a network of connected cracks or grooves without a definite orientation is formed on the surface (crazing). The surface resembles a wrinkled orange or an elephant's skin. The process becomes slower as irradiation continues. Destruction of the vulcanizate generally does not occur, but the surface can become completely brittle so that it can no

longer bind the white filler (chalking). Crazing occurs only in light-colored vulcanizates, not in pigmented ones or in those filled with carbon black. It is caused by light- catalyzed oxidation of the vulcanizate surface. High-energy, short-wavelength light is more effective than long-wavelength light. If the high-energy blue and violet rays are filtered off, hardly any damage occurs. Therefore, yellow and red pigments have a favorable effect here. The protective effect of carbon black results from its complete light adsorption.

Frosting. Frosting is a special aging effect. Previously glossy or colorless rubber surfaces become mat or acquire a white coating under certain, not fully understood conditions. The frosting phenomenon occurs in a warm, damp, ozone- containing atmosphere, and only in vulcanizates with white fillers, mainly silica. Acidic accelerators promote the effect, as do thiurams and dithiocarbamates, whereas basic accelerator systems appear not to [67, 68].

3.2. Classification and Types of Antidegradants [69 – 75]

(see also → Antioxidants)

The resistance of a vulcanizate toward the aging effects described is determined primarily by the elastomer forming the basis of the compound. The cross-linking system, the cross-link density, and to a lesser extent, the antidegradant used also affect aging resistance.

The mechanism of action of the antidegradant depends on the presence of active hydrogen-atoms in the molecule. These are present in the form of OH, NH, and SH groups, which act as chain terminators in the radical chain reaction initiated by oxygen, for example. The radical that is formed from the antidegradant after hydrogen splitting is resonance stabilized. Because it is very low in energy and sterically hindered, it cannot initiate a new radical chain reaction. It either reacts with another antidegradant radical (dimerization) or combines with a peroxy or alkyl radical (see Fig. 7). In a single autoxidation reaction chain about 10 – 100 oxygen molecules can be transferred to the polymer substrate. The antidegradant never competes with the substrate with regard to direct oxygen absorption. Much higher dosages would be necessary for this.

Figure 7. Mechanism of action of antidegradants

For *ozone protection* a scavenger protective film mechanism is assumed, based on the work of Lattimer et al. [76 – 78]. The antiozonant competes with the double bonds of the polymer for ozone. The effectiveness of the antiozonant also depends on its mobility.

With a few exceptions, antidegradants can be subdivided into mono- and oligofunctional aromatic amines, mono- and oligofunctional phenols, and heterocyclic mercapto compounds. For the user, their different mechanism of action is more important. Correspondingly a differentiation is made among *antioxidants*, *antiozonants*, and *anti-flex- cracking agents*. In addition, the action of the antidegradants against discoloration of the vulcanizate itself and against contact staining is also important.

Staining products are more effective than nonstaining ones, but this is not always true.

Aromatic amines are generally staining antidegradants, and phenols nonstaining ones.

The following groups can be distinguished.

3.2.1. Staining Antidegradants that Act as Anti-Flex-Cracking Agents and Antiozonants

p-Phenylenediamines substituted at nitrogen are the most effective antioxidants, anti-flex- cracking agents, and antiozonants under static and dynamic stress. They increase the critical energy necessary for the formation of ozone cracks under static conditions. Cracking therefore occurs only at greater elongation. At the same time the cracking rate under static and dynamic stress is decreased [79].

The range of activity of individual *p*-phenylenediamines (**28**) depends on the nature and size of the substituents on the nitrogen atoms.

Symmetrical *N*,*N*′-diaryl-*p*-phenylenediamines are very effective antidegradants. For example, *N*,*N*′-di-β-naphthyl-*p*-phenylenediamine (known internationally as DNPD) is the most powerful antioxidant known for rubber. However, it is no longer produced for toxicological reasons. Because of the size of the substituents its mobility in rubber is very low, so that DNPD is, in practice, not transported to the surface to protect against fatigue and ozone. If smaller substituents are used (e.g., *N*,*N*′-ditolyl-*p*-phenylenediamine, DTPD), the mobility is somewhat higher, and thus the protection against fatigue and ozone is better, but the compound is a poorer antioxidant [80, 81]. *N*,*N*′-Diphenyl-*p*-phenylenediamine (DPPD) [*74-31-7*] shows similar effects. Because of its low solubility in rubber, and therefore its greater tendency to bloom, it is seldom used for rubber.

Of the symmetrical dialkyl derivatives, *N*,*N*′-diisopropyl- and *N*,*N*′-di-*sec*-butyl-*p*-phenylenediamine are particularly effective in counteracting ozone cracking. They are, however, not used in rubber because of their high volatility and skin irritating action. *N*,*N*′-Bis(1,4-dimethylpentyl)-*p*-phenylenediamine (77PD) [*3081-14-9*] or *N*,*N*′-bis(1-ethyl-3-methylpentyl)-*p*-phenylenediamine (DOPD) exhibit better properties. Compared with alkylaryl-*p*-phenylenediamines, the symmetrical dialkyl compounds have the advantage of being particularly good antiozonants under static stress. Their disadvantages are their relatively low protective action against oxygen and heat, their unfavorable effect on onset of cure, and their high volatility.

Under static and dynamic stress, *N*,*N*′-alkylaryl compounds exhibit greatest activity when the alkyl group is an isopropyl or *sec*-butyl group and the aryl is a phenyl group. The most active compound is *N*-isopropyl-*N*′-phenyl-*p*-phenylenediamine (IPPD) [*101-72-4*]. *N*-1,3-Dimethylbutyl-*N*′-phenyl-*p*-phenylenediamine (6PPD) [*793-24-8*] is less volatile, causes less water elution from the rubber article (e.g., tires), and thus has a prolonged activity. However, it is a little less active than IPPD, and protection against fatigue is somewhat lower. *N*-1,4-Dimethylpentyl-*N*′-phenyl-*p*-phenylenediamine (7PPD) [*3081-01-4*] is comparable to 6PPD but less important in market terms. Sensitization on skin contact

is possible with IPPD, so labeling as harmful to health is obligatory. This does not apply to 6PPD. IPPD is therefore being increasingly replaced by 6PPD. Longer-chain alkyl groups (e.g., 2-methylheptyl groups) reduce the volatility still further, but the action against ozone and flex cracking (fatigue) is considerably less at the same dosage (in terms of weight) [82].

An addition to *p*-phenylenediamines, 6-ethoxy-2,2,4-trimethyl-1,2-dihydroquinoline (**29**) (ETMQ) [*95-31-8*] also belongs to the group of agents that protect against autoxidation, fatigue, and ozone. Its activity against static and dynamic cracking is comparatively weak.

29

Long-term protection is becoming increasingly important technologically. Volatility and water elution play a decisive role, particularly in truck tires that are retreaded many times. Here, combinations of 6PPD and DTPD have proved successful. Antidegradants based on alkylaryl-*p*-phenylenediamines, which are or can be polymer bound, have also been investigated. In agreement with the scavenger protective film model, these compounds are very good antioxidants, average anti-flex-cracking agents, and poor antiozonants [83 – 87]. To better understand the action of *p*-phenylenediamines, the effect of substituents on the protective function was also investigated. The arylalkyl-substituted NH group is primarily responsible for antiozonant properties, and the bisaryl-substituted NH group for protection against fatigue. Antioxidant properties are comparable for the two groups [88].

3.2.2. Staining Antidegradants with Protection against Fatigue, but Not against Ozone

The diarylamines (**30**), such as phenyl-α-naphthylamine (PAN) [*90-30-2*], phenyl-β-naphthylamine (PBN) [*135-88-6*], and substituted diphenylamines, such as octylated diphenylamine (ODPA) or styrenated diphenylamine (SDPA) [*68442-68-2*], are important antidegradants.

This group protects mainly against oxygen and heat. Because traces of carcinogenic β-naphthylamine are always present in PBN, PBN is seldom used. In addition, PBN has the disadvantage of blooming because of its low solubility in rubber. The level of activity of all antioxidants in this group is about the same in tire rubbers (natural rubber, synthetic polyisoprene, polybutadiene, and styrene – butadiene rubber). ODPA and SDPA are significantly more active in polychloroprene than the other products. In general, ODPA, SDPA, and other diphenylamines offer the best protection against oxygen and heat for chloroprene rubbers.

PAN, PBN, ODPA, and SDPA are effective anti-flex-cracking agents, although not to the same extent as *p*-phenylenediamines. PAN and PBN give about the same protection; that of ODPA and SDPA is a little lower. However, rubbers respond differently to these antidegradants. In NR and IR the activity is high, whereas in SBR and BR these products provide low protection. The tendency of PAN and PBN to stain is lower than that of *p*-phenylenediamines. However, it is still high enough that these antidegredants can only be applied in dark compounds. ODPA and SDPA are weakly staining products (yellow to brownish yellow); only weak contact staining is observed. Thus, ODPA and SDPA can be used

without any problem for brown and red vulcanizates.

3.2.3. Staining Antidegradants with Little or No Protection against Fatigue and None against Ozone

As has already been mentioned, for protection against fatigue or ozone, a certain mobility of the antidegradant molecule in the substrate is necessary. Products in which this mobility is limited are antidegradants only in the narrow sense.

For example, *N*,*N′*-di-*β*-naphthyl-*p*-phenylenediamine (DNPD) protects only against oxidation, not ozone or fatigue. 2,2,4-Trimethyl-1,2-dihydroquinoline (TMQ) [*26780-96-1*] is present in oligomeric form (**31**) and thus not very mobile.

31

It is a good antioxidant, but gives low protection against fatigue. Because of its oligomeric form, TMQ is nonvolatile and is therefore an antidegradant with effective heat protection. Despite its low migrating capacity, vulcanizates containing TMQ can give rise to contact staining. This is, however, lower than in the case of PAN. A special feature of TMQ is its relative inertness toward cross-linking peroxides. It can therefore be used as an antidegradant in peroxidically cross-linked EPDM, EPM, or PE.

Diphenylamine – acetone condensation products (ADPA) [*68412-48-6*] are also effective heat-protection agents, but they have been forced off the market to a great extent by TMQ.

3.2.4. Nonstaining Antidegradants with Protection against Fatigue or Ozone

Nonstaining antidegradants are generally inferior to the staining products under different aging stresses.

Aralkylated phenols (**32**), e.g., styrenated phenols (SPH) [*61788-44-1*], and alkylated, styrenated phenols are nonstaining antioxidants that protect against fatigue but not ozone.

$n = 1,2,3$

32

These monofunctional phenols are relatively low priced and exhibit medium-strong protection toward oxygen and heat. Protection against flex cracking is not comparable with that of *p*-phenylenediamines, but is higher than that of other phenols. These products impart good protection against crazing to light colored vulcanizates.

A range of new products has been developed and presented as nonstaining antioxidants with protection against ozone. None of them are used successfully in the market, however.

3.2.5. Nonstaining Antidegradants without Protection against Fatigue or Ozone

Certain products protect against oxygen and heat, crazing, and to some extent, heavy-metal rubber poisons but show little or no effect against flex cracking, and none against ozone cracking. These antidegradants are mostly phenols, but some are heterocyclic mercapto compounds.

BHT

33 **34**

35 **36**

2,4,6−Substituted monophenols

Of the *2,4,6-substituted monophenols* (**33**–**36**), 2,6-di-*tert*-butyl-4-methylphenol [*128-37-0*] (**33**) (BHT) is widely used. However, because of its high volatility, it is an effective antioxidant only at relatively low temperature. Phenols, such as 6-*tert*-butyl-2,4-di-

methylphenol (**36**), 2,4-dimethyl-6-(α-methylcyclohexyl)phenol (**35**), and 2,6-di-*tert*-butyl-4-methoxymethylphenol (**34**) exhibit better thermal stability and thus considerably better protection. Other substituted monophenols, whose structures have not been published, have been marketed by various companies.

BPH
37

38

39

40

41

42

43

Of the *bifunctional phenols*, 2,2′-methylenebis(6-*tert*-butyl-4-methylphenol) (BPH) [*119-47-1*] (**37**), 2,2′-methylenebis(6-α-methylcyclohexylphenol) (**38**), 2,2′-isobutylidenebis(4,6-dimethylphenol) [*33145-10-7*] (**39**), and 4,4′-butylidenebis(2-*tert*-butyl-5-methylphenol) [*85-60-9*] (**40**) offer excellent protection against oxygen. However, with the exception of the two last-named compounds, prolonged illumination of the vulcanizate can produce a pink coloration. 2,2′-Methylenebis(6-cyclohexyl-4-methylphenol) (**41**) or the corresponding 6-*tert*-butyl-4-ethylphenol derivative (**42**) and 4,4′-thiobis-(6-*tert*-butyl-3-methylphenol) [*96-69-5*] (**43**) [89, 90] have a lower staining tendency but are less active.

The reaction product of dicyclopentadiene and 2-*tert*-butyl-4-methylphenol is also a bifunctional product. It has a low staining tendency, particularly in an oxidizing medium (e.g., when latex articles are treated with oxidizing cleaning agents). Its main applications are consequently also in the latex area. The mono- and bifunctional phenols named are added as antioxidants in the compounding of solid rubber, and they are also used as so-called *stabilizers* in polymer production. Polymers can be damaged thermooxidatively in processing (e.g., during drying) and must therefore be protected. The quantity of stabilizer added here is lower than in later compounding. Besides direct protection during production, stabilizers also protect the polymers on storage until use. The stabilizers are generally pure antioxidants, but combinations of nonstaining antioxidants with organic phosphites such as tris(nonylphenyl) phosphite (TNPP) are also used. A disadvantage of phosphites is their low stability to hydrolysis. Liquid stabilizers are preferred for better handling. One example of these is 6-methyl-2,4-bis(octylthiomethyl)-phenol [*110553-27-0*] (**44**).

44

Trifunctional or *polyfunctional phenols* are characterized by extremely low volatility and are therefore used for polymers that are processed at high temperature. Examples of trifunctional phenols are tris-1,1,3(5′-*tert*-butyl-

4′-hydroxy-2′-methylphenyl)butane (**45**), and 1,3,5-trimethyl-2,4,6-tris(3′,5′-di-*tert*-butyl-4′-hydroxybenzyl)benzene (**46**). An example of a polyfunctional phenol is pentaerythrityl-tetrakis[3-(3,5-di-tert-butyl-4-hydroxyphenyl) propionate] (**47**).

45

46

47

48

These phenols are used less with diene rubbers and mainly with polyolefins such as polyethylene and polypropylene. A monophenol of low volatility, octadecyl-3-(3,5-di-*tert*-butyl-4-hydroxyphenyl) propionate (**48**) is also used. In PE or PP these phenols are used alone or in combination with nonvolatile, hydrolysis-stable, organic phosphites [e.g., tris(2,4-di-*tert*-butylphenyl) phosphite (**49**)].

49

The phosphites are also known as processing stabilizers because they protect thermoplastics from polymer degradation during multiple extrusion.

Mercaptobenzimidazole (MBI) (**50**), its zinc salt (ZMBI) (**51**), 4- and 5-methyl-2-mercaptobenzimidazole (MMBI), and their zinc salts (ZMMBI) are antidegradants of average activity.

MBI
50

ZMBI
51

However, they are generally not used alone. They are of great importance because they act synergistically with almost all other antidegradants (i.e., the activity of the combination is greater than the sum of the activities of the individual antidegradants).

All products in this group give some protection against copper and manganese rubber poisons. MBI and MMBI or their zinc salts exhibit low activity when applied alone, while a combination of MBI and a bisphenol such as BPH, for example, results in synergistic action. These combinations are therefore always recommended when strong protection against rubber poisons and favorable staining behavior are required. The mercaptobenzimidazoles can be regarded as tautomeric thioureas. This explains why they also act as accelerators, particularly in CR vulcanization. The zinc compounds have less effect on vulcanization kinetics. Like TMQ, MBI and MMBI and their zinc salts interfer in cross-linking with peroxides only to a minor extent.

3.2.6. Nonstaining Antiozonants without Protection against Aging

The production of ozone-resistant, light colored rubber articles is a challenge for the compounder. Within certain limits, light colored rubber articles can obtain some physical protection by the addition of *waxes*. Waxes bloom on the surface of the article above a certain concentration (in natural rubber, ca. 0.8 %) and form a physical barrier against attack by ozone. If the film is damaged, the protective action is lost in that location, and the cracks formed there are often wider and deeper than they would be without the wax. Microcrystalline waxes show improved

action, particularly at high temperature. Waxes alone have no effect in counteracting dynamic crack formation.

The *combination of wax and antidegradants* can lead to considerably improved protection against aging. Antiozonants, antioxidants, and anti-flex- cracking agents are enriched at the vulcanizate surface by the migration of antiozonant waxes. This is most important for good protection against ozone.

Another possibility for the compounder involves *blending diene rubbers with ozone-resistant polymers*. Blends of NBR with PVC are commercially available, but blends of diene rubbers with CR or EPDM are also worth considering. However, attention must be paid to compatibility.

Besides some benzofuran derivatives, special ethers (**52**) and acetals (**53**) with olefinic double bonds have been found to be *chemically active, nonstaining antiozonants*.

52

53

Since they contain no active hydrogen, they do not act as chain terminators in radical chain reactions, but the olefinic double bond in the reagent competes for ozone with the double bonds in the rubber. In diene rubbers such as NR and SBR, these special compounds are active only in combination with wax. Without addition of wax they can be used only in CR, halogenated polymers (e.g., HIIR, CM) and its blends.

3.2.7. Other Antidegradants

Polymers containing ester groups, such as ethylene – vinyl acetate copolymers, and also polyurethanes, can be attacked by moisture, acid, base, and sometimes elevated temperature. By the addition of, for example, polycarbodiimides these effects can be inhibited and the durability considerably improved.

3.3. Choice of Antidegradants

An overview of the spectrum of activity of the most important antidegradants is presented in Table 3. The table can be used to estimate which products are suitable for different requirements and for a particular combination.

Nearly all antidegradants can be employed to prevent *autoxidation* of vulcanizates, with the exception of the special antiozonants without protection against aging, or agents giving protection against hydrolysis and light.

The number of suitable *anti-flex- cracking agents* is more limited. An anti-flex- cracking agent is generally active against autoxidation, while the reverse is not true.

There are even less suitable *antiozonants* available. Staining antiozonants are mainly also anti-flex- cracking agents, but not every anti-flex- cracking agent is an antiozonant. Apart from waxes and nonstaining antiozonants, antiozonants are generally also active against heat and oxygen. However, not every antioxidant is active against ozone cracking.

The *level* of antidegradants in the vulcanizates depends on the usage condition of the compound and on the antidegradant itself. Antidegradants show a pronounced plateau effect in their action against autoxidation (i.e., above a certain level the protection against autoxidation is not improved by increasing the dosage). Typical levels are between 0.5 and 2.5 phr. For protection against ozone or fatigue, a plateau effect occurs only beyond 4 – 6 phr; the activity increases continuously with increasing level. The usual levels are therefore higher, between ca. 1.0 and 3.5 phr.

The protective effects achieved are more pronounced in natural rubber than in synthetic, partly because of the generally better resistance of synthetic rubber to aging, and partly because of the stabilizers already added during production, which act as antidegradants. Both staining antidegradants (e.g., *p*-phenylenediamines) and nonstaining ones (e.g., mono-, bi-, and polyfunctional phenols) are used as stabilizers. The dosage depends on the activity of the substance and the desired protective effect, and is between 0.1 and 1.0 %. Staining stabilizers are almost always superior to nonstaining ones, particularly with regard to heat resistance and inhibition of

Table 3. Spectrum of activity of important antidegradants

gel formation. There are also special stabilizers (e.g., aryl phosphites), which are not antidegradants for vulcanizates.

Producers and Trade Names. The following are producers of antidegradants and stabilizers for rubber: Akzo (Permanax), Bayer (Vulkanox), Bozzetto (Anox), Chemische Werke Lowi (Lowinox), Ciba-Geigy (Irganox, Irgafos), Goodrich (Good-Rite), Goodyear (Wingstay), Kawaguchi (Antage), Monsanto (Santoflex, Santowhite), Raschig (Ralox), Seiko (Nonflex), Sumitomo (Antigene, Sumilizer), and Uniroyal Chemicals (Flexone, Naugard).

4. Fillers and Pigments

4.1. Typical Properties and Types of Fillers [91 – 96]

4.1.1. Action of Fillers

The properties of industrial rubber compounds and their vulcanizates are determined not only by the nature and quantity of the polymers used, the cross-linking system, the plasticizers, and the antidegradants but also by the nature and quantity of the fillers employed. Non-self-reinforcing rubbers such as SBR and BR give unsatisfactory and hardly usable vulcanizates without the addition of reinforcing fillers (white fillers or carbon blacks).

Fillers are classified with regard to their chemistry, first into white fillers and carbon blacks, and second into natural products and synthetic ones. Technologically, a distinction is

made between active or reinforcing fillers and inactive or extender fillers. The former are used to achieve particular vulcanizate properties; the latter, to make the compound cheaper (to extend it). The varying reinforcing effects of fillers *enhance* a range of vulcanizate properties, such as toughness, stress, tear resistance, compound viscosity, and hardness, whereas other properties, such as elongation at break and impact resilience are *impaired.* The activity of a filler is determined by particle size (the smaller the size, the greater is the activity), the geometrical shape of the particles (structure), and the chemical composition. If the dependence of vulcanizate properties on the quantity of filler is investigated, a steady change in properties is observed for inactive fillers, whereas for active fillers, as might be expected, increasing the proportion of filler leads to a maximum, which is characteristic in height and position for the individual filler (see Fig. 8).

At the same level, active fillers give harder vulcanizates, higher tensile strength, better tear resistance, and lower abrasion loss than inactive ones. On addition of inactive to medium-active fillers the *elastic properties* of vulcanizates deteriorate only slightly; they are even improved with finely divided zinc oxide. With active fillers, worsening of elastic properties is often observed. A comparison of activity of various fillers gives conflicting results with regard to modulus. Highly active precipitated silicas only moderately improve the modulus because of their special effect on the vulcanization behavior, and accordingly would have to be classified as semiactive. This would contradict their other behavior in rubber. Besides vulcanizate properties, the mixing temperature during production and the compound viscosity are measures of the activity of a filler. The more sharply the *viscosity* decreases with an increasing proportion of filler, the more active the filler is. For compounding, too high a viscosity is a disadvantage, not only because of the high mixing energy costs, but above all because further processibility (extrusion, calendering, injection molding, etc.) is impaired. A highly active filler can therefore only be added in smaller quantities than an inactive or semiactive one. For classification of a filler, the entire property profile of the green compound produced with the filler and its vulcanizates must be considered.

Figure 8. Effect of active and inactive fillers
A) On tensile strength; B) On abrasion; C) On tear resistance of natural rubber

If a filler – rubber mixture is extracted with a suitable solvent (benzene, toluene), and after drying of the the extraction residue, a hard, brittle gel is obtained, which contains all the filler. The rubber content of this gel is known as *bound rubber*. The quantity of bound rubber formed on mixing depends on many factors, such as type of filler, degree of filling, polymer type, mixing technique, and extraction conditions. In the case of carbon blacks, bound rubber is a measure of filler activity, but it is not used for assessment, unlike other physical properties such

as surface area and structure, whose dependence on the compound and vulcanizate properties are known.

4.1.2. Properties of Fillers and Their Significance [97]

The optimum level of fillers to achieve a certain compound property can be found by determining the vulcanizate properties as a function of the degree of filling. Since this method is very laborious and time- consuming, a series of analytical methods are available that give the specialist an indication of how the filler is likely to behave in the rubber. The analytical test methods are found in ASTM, DIN, or ISO standards.

The following important test methods are used to characterize fillers:

The *specific surface area* is determined by nitrogen or iodine adsorption. For inactive fillers, BET values between 0 and 10 m^2/g are found; for semiactive ones, values between 10 and 90 m^2/g; and for active ones, values between 90 and 250 m^2/g. The cetyltrimethylammonium bromide (CTAB) number is used as a measure of the nonporous surface area. Occasionally it is regarded as the more exact way of describing the reinforcing effect.

The primary *particle size* can only be derived inexactly from a determination of the surface area. The smallest physically determinable filler particles, so- called primary particles, can be measured by means of electron microscopy. For active, precipitated silicas the primary particle diameter is in the range 15 – 20 nm. In the case of carbon blacks and active silicas and silicates, the primary particles collect together via the so- called primary bond to form aggregates, which in turn form agglomerates (secondary structure) through van der Waals forces. This secondary structure can be destroyed relatively easily because of the relative weakness of the van der Waals forces. This is the case when carbon blacks or silicas and silicates are mixed into rubber and dispersed. At sufficiently high shearing forces and adequate mixing time, the aggregates form the smallest filler particles present in the rubber. The mixing process is often stopped before this situation is reached. The size of the agglomerates and their distribution in the filler are usually determined by laser beam scattering.

The *adsorption of liquids* by fillers can give indications of the structure of the filler and thus its activity. In the past, mainly oil adsorption was determined, but more recently dibutyl phthalate (DBP) adsorption is preferred. Unlike carbon blacks, the activity of precipitated silicas and silicates in rubber cannot be unambiguously described and classified by using the DBP number. Silicas and silicates with differing reinforcing properties can give the same results on DBP adsorption. For carbon blacks, DBP numbers between 60 and 150 mL/100 g are found; for active precipitated silicas the values are between 150 and 250 mL/100 g.

The *tint strength* is actually a colorimetric property of carbon blacks. It is a comparison of the color strength of carbon blacks with a white pigment (zinc oxide). Since the tint strength is affected by particle size – particularly particle-size distribution – and also by the structure of the carbon black, conclusions about the activity can be drawn. The more finely divided the carbon black is, the greater is the tint strength. Lower structures (i.e., carbon blacks with a lower degree of aggregation, see → Carbon) have higher tint strengths.

The pH of the rubber compound influences vulcanization kinetics. Acidic compounding ingredients delay the onset of cure, while basic ones accelerate it. For this reason the *pH of fillers* in an aqueous dispersion is determined. In all classes of fillers (carbon blacks, natural and synthetic white fillers), both acidic and basic products are found. The gas carbon blacks are acidic because of their oxidized surface, while furnace carbon blacks are normally basic. Precipitated active silicas are neutral to weakly acidic, and synthetic silicates are basic (pH 9 – 12).

The methods of determining *pellet hardness* (usually only for pelletized carbon black types) and *sieve residue* (various possible methods) play an important role in the processing of fillers.

Pellet Hardness. The pellet hardness gives indications of possible problems with dispersion. Too high a hardness can give rise to undispersed carbon black areas in the compound and thus defects in the finished article and its possible rejection. However, pellets that are too soft are also undesirable. During transportation and storage of the filler a high content of fines is formed, which can result in dust exposure at the

place of mixing, on weighing out, or possibly in automatic dosing systems. The fines content and the pellet abrasion are therefore measures of transport stability and conveyability.

Sieve Residue. For the granular active silica types also used in the rubber industry, corresponding considerations apply. Granulate hardness has not yet been determined successfully because of technical measuring difficulties. The fines content in the *Rotation and Tapping* (*ROTAP*) *dry sieve analysis* gives a first indication of transport stability. Certain values may not be exceeded because dust problems can also arise at the workplace in the processing industry.

For powder fillers the sieve residue gives indications of possible processing problems through grit or undispersed filler particles. These cause defects such as holes or unevenness, particularly in thin-walled articles (e.g., profiles, hosing, membranes) which can also lead to rejection of the article.

Bulk and Tapped Density. To determine the space requirement of fillers the bulk and tapped densities are measured. They are important for the volumes necessary for transport and storage, and can also give an indication of dispersion time. A filler with a lower bulk or tapped density requires a longer time for incorporation into the rubber because smaller shearing forces are built up. The specific densities of fillers, as well as those of all other compounding ingredients, are needed for calculating the optimal degree of filling of internal mixers and the density of the resulting compound.

Other filler properties, which are used only occasionally for special types of rubber, are dealt with in that particular section, if important.

Fillers can be classified simply as *carbon blacks* and *white fillers*. The latter include many natural and synthetic products, such as pyrogenic and precipitated silicas, precipitated aluminum and calcium silicates, zinc and magnesium carbonates, calcium carbonate (natural and synthetic), calcium and barium sulfates, soft and hard clays, calcinated clay, silica, talc, barytes, aluminum hydrate, metal oxides, and titanium dioxide. A classification scheme is given in Figure 9.

4.2. Carbon Blacks [98 – 102]

(→ Carbon, Chap. 6)

Chemically, industrial carbon blacks consist almost exclusively of carbon. However, simply using the chemical symbol C would not describe carbon blacks adequately to the user. For characterization a number of physical and chemical properties are therefore determined, which give the specialist an indication of the activity and compounding behavior in polymers. Small proportions of oxygen, hydrogen, nitrogen, and sulfur, and traces of metals in the lower ppm range, can be determined by chemical analysis. Oxygen- containing groups, such as carbonyl, carboxyl, pyrone, phenol, quinone, lactol, and ether groups, can occasionally be determined quantitatively on the surface of carbon blacks. The content of nitrogen and sulfur depends on the raw materials used.

Carbon blacks are produced either by *incomplete combustion* of crude petroleum, natural gas, and tar oil products or by the *thermal cracking* of acetylene and other hydrocarbons. The following are produced by *incomplete combustion:* lampblack, channel black, gas black, and furnace black. Thermal, acetylene, and electric arc blacks are produced by *thermal cracking*.

The annual production capacity for carbon blacks is more than 6×10^6 t worldwide. Furnace blacks are the most important group, accounting for more than 95 %. The furnace black process was developed in the 1920s and differs from the other processes mainly in that the incomplete combustion for carbon black production takes place in a closed reactor. In this process, the small number of basic types could be diversified into a large number of different types by using alkali-metal compounds, which have an effect on the structure of carbon blacks.

In the rubber industry, furnace blacks have forced the others almost completely out of the market. In the past, *thermal blacks* and the *channel blacks* were quite important. For environmental reasons (high emissions), only limited quantities are still produced by these processes. *Acetylene blacks* are important as conducting blacks because of their particular purity. To achieve comparable conductivity of a compound, only small quantities of these types are needed compared to standard types. Generally the conductivity of a filled polymer increases

Figure 9. Classification of fillers

with increasing specific surface area and increasing structure of the carbon black.

In the past, carbon blacks were characterized for the rubber industry according to their behavior in the rubber compounds. Carbon blacks, which showed particular resistance to abrasion in compounds, were specified as *high-* or *superabrasion furnace* (HAF or SAF); others with particularly good behavior in extrusion compounds, as *fast-extrusion furnace* (FEF), for example. The ASTM specification D 1765 has now become widely used (Table 4). It consists of a letter that describes the vulcanization rate (N for normal, S for slow) and three numbers, the first being an index of the primary particle size. The physical and chemical characteristics are based on the carbon black currently used as a comparison, International Reference Black 6 (IRB 6). This carbon black was produced in a single production campaign after agreement with other producers. After this comparison carbon black has been consumed a new one will be produced, which will then have the specification IRB 7, etc.

According to the ASTM scheme, carbon blacks are characterized principally by iodine adsorption and nitrogen surface area, which are measures of the particle size and activity of the carbon black, and the DBP adsorption (structure) (→ Carbon). The differences in specific surface area and structure are clearly reflected in the technical rubber properties. Increasing iodine adsorption or nitrogen surface area is associated with increased reinforcing action [103]. *High-structure carbon blacks* are evenly distributed in the compound. They bring about in- creased compound viscosity and low die swell with smooth extrudate surfaces, high modulus, increased hardness, and improved abrasion resistance in the vulcanizate. In the 1960s the high-structure carbon blacks dominated the field of abrasion-resistant tire treads. At the beginning of the 1970s, so- called *improved* or *new-technology carbon blacks* were developed as a result of a new technology in furnace black production [104 – 107]. A characteristic of this new generation compared to standard carbon blacks is improved abrasion resistance of the tire treads at the same iodine adsorption of the carbon blacks. The difference between these and the normal carbon blacks with regard to physicochemical properties lies in the nonporous carbon black surface (CTAB adsorption).

Table 4. Extract for carbon black classification according to ASTM 1765

ASTM specification	Iodine adsorption, g/kg	DBP adsorption, mL/100 g	Nitrogen-surface area, m^2/g
N 115	160	113	145

N 650	36	122	38
N 762	27	65	28
N 765	31	115	31
N 990		43	9

Carbon blacks with *low structure* are characterized by lower heat buildup under dynamic stress (hysteresis), high tensile strength and tear resistance, good resistance to flex cracking, and low modulus.

Occupational Health. Industrial carbon blacks do not belong to the group of hazardous substances or goods. Years of experience by carbon black producers and the processing industry have shown that no health hazards or damage should be expected from them. Detailed investigations in Europe and the United States have shown that industrial carbon blacks do not cause any structural damage to the lungs. Irritation of the eyes and mucous membranes has also not been observed. Therefore, during production and processing only the general dust limits must be adhered to. These are 3.5 mg/m^3 in the United States (TLV) and 6 mg/m^3 in Germany [108].

Producers and Trade Names. The largest producers of industrial carbon blacks are Cabot (Elftex, Vulcan), Columbian Carbon (Startex, Furnex), and Degussa (Corax, Printex).

4.3. White Fillers

Silicon as a carrier of "inorganic life" occurs in nature almost exclusively in the form of crystalline solids in approx. 800 different siliceous minerals. In the evolutionary history of man, there are numerous indications of the omnipresence of silicates in our natural habitat. Siliceous minerals were either utilized by processing natural silicate deposits, e.g. clay, porcelain, glass or enamel, or obtained by means of chemical conversion (silica, silicones, ceramics). The reason for Degussa dealing with the siliceous chemicals was the company's involvement in the field of carbon black. In addition to their classic application as black pigment, carbon blacks were also increasingly used as active fillers in the rubber industry, in particular in the manufacture of automobile tires. Because the starting material for carbon black at the time (in the 1940s) – natural gas – was not available in sufficient quantities in Germany, a substitute was sought which could be prepared from indigenous starting materials. The concept of 'white carbon black' was born and research into the manufacture of siliceous fillers commenced. The idea to apply the manufacturing method for carbon black to volatile silicon compounds (pyrogenic silica, Aerosil) also originates from that time [215].

4.3.1. Precipitated Silicas

As described above, fine *silicas* can be produced by a pyrogenic reaction (see Section 4.3.2) or by precipitation. *Silicates* are manufactured by a precipitation process. It is an interesting task to precipitate silicas and silicates from aqueous media. The methods are so variable that different products customized for the respective application are attainable. Manufacturers and users of fine silicas and silicates require analytical characteristic values in order to compare the various products [216]. Owing to the great differences in chemical composition of silicas, silicates, and other natural substances such as chalk or siliceous minerals, the characterization usually commences with chemical analysis, which provides important information on the product composition, the main and particularly the secondary constituents. One significant constituent of precipitated silicas and silicates is water, which occurs in various quantities, either chemically bonded or adsorbed. The specific surface area, mean particle size, particle size distribution, pH and absorption of certain oils all play a significant role in the fine products and thus have to be determined. These somewhat "classic" methods of analysis and a number of new methods for characterizing silicas and silicates will be dealt with in greater detail in Section 4.3.1.3. The versatility of fine silicas and silicates is attributable to a variety of fundamental properties. In chemical terms, they are largely inactive and exhibit high thermostability. Targeted modification of the silica surface with organic silicone compounds (see Section 4.3.1.3) converts "water-friendly" or hydrophilic silicas into "water-repelling" or hydrophobic products. These hydrophobic properties have proven to be very useful for certain applications, e.g., in silicone rubber or for defoaming liquids. The oldest application of "white" silicas and silicates, i.e. in shoe soles and technical rubber articles, and the use of silicas in modern automobile tires will be discussed later.

4.3.1.1. Production

Precipitated silicas have only been produced since the 1940s but they have grown to become the most important group of silica products on the basis of production tonnage. The worldwide production capacity of precipitated silica in 1999 was ca. 1 100 000 t, compared to ca. 400 000 t in 1970 [217]. The European production volume for precipitated silica for the year 2000 was 285 500 t [218].

The raw materials used for the industrial production of precipitated silicas are alkali (preferably sodium) silicate solutions, and acid. Silica is precipitated through a reaction of both components. Depending on the intended application of the silica, precipitation parameters such as feed rates, stirring, shearing, temperature, pH, alkali content, etc., can be adjusted allowing for a wide range of silica products with different characteristics, such as specific surface areas ranging from approximately 25–700 m^2/g. Typically, *precipitated silicas* are synthesized under alkaline conditions at pH values >7, while *silica gels* are typically produced under acidic conditions.

Industrially produced synthetic precipitated amorphous silicas are still made today by precipitation from diluted sodium or potassium silicate solutions with the aid of mineral acids such as sulfuric or hydrochloric acid, or by using carbon dioxide. In case of the use of sodium silicate and sulfuric acid the reaction follows Equation 1

$$Na_2O \times 3.3\,SiO_2 + H_2SO_4 \rightarrow 3.3\,SiO_2 + Na_2SO_4 + H_2O \quad (1)$$

In general a module of 3.2-3.5 — the module indicates the ratio between disodium monoxide and SiO_2-content in the sodium silicate — is used in order to reduce formation of byproducts. In all cases a corresponding byproduct is formed which can be sodium sulfate, sodium chloride or sodium carbonate, depending on the acid component employed. If potassium silicate is used, the corresponding potassium salts develop. These byproducts must be removed in the downstream process.

Principally, the polymerization reaction follows the route given in Equation 2

$$\text{Monomer} \rightarrow \text{Dimer} \rightarrow \text{Cyclic molecule} \rightarrow \text{Particle} \rightarrow \text{Precipitated silica} \quad (2)$$

The exact timing of the aggregation in the process and the duration of the particle growth can be controlled by the salt concentration, e.g., by adding sodium sulfate. The underlying mechanism of the process is described in detail in [219].

During the reaction, primary particles are first formed in the reactor; later these particles react with each other, accompanied by dehydration, to form aggregates. Within the aggregates, the primary particles are linked together via siloxane (Si-O-Si) bonds. During this process, the aggregates are deposited to form larger units, or agglomerates. In these agglomerates, the aggregates are held together by hydrogen bonding or van der Waals interactions which are considerably weaker than siloxane bonds. A state of equilibrium, which is dependent on the process conditions and can be easily influenced, is reached between the aggregates and agglomerates (Fig. 10).

Figure 10. Particle formation during precipitation

The complete industrial production process consists of the following steps: precipitation, filtration, drying, grinding, and, in some cases, compacting and granulation (see Fig. 11):

Figure 11. Industrial production process of Precipitated Silica

So far only batch precipitation processes have attained economic importance [220, 221], although continuous precipitations have also been reported [222].

The separation of the silica from the reaction mixture and the removal of the salts contained in the precipitate is carried out in filter aggregates such a rotary filters, belt filters, or chamber-, frame-, and membrane-filter presses.

Since the solid content of the filter cake products is only 15 – 25 %, about 300 to 600 kg of water must be evaporated for each 100 kg of final product. Depending on the desired properties of the end product, drying is carried out in spray, nozzle spray, plate, belt, or rotary driers. Special product properties can be achieved by spray drying the filter cakes after redispersion in water or acid [223, 224]. Figure 12 shows scanning electron micrographs of a nozzle spray-dried, unground silica and a conventionally dried, ground silica.

Various mills and, if required, classifiers [225] are used to control the desired fineness of the particles. Special degrees of fineness can be achieved by air-jet or mechanical grinding [226]. The silica is separated from the air in cyclones or filters.

Processes for the compression and granulation of precipitated silica have been developed [227, 228] to reduce the volume for transportation and for certain uses and also to decrease the formation of dust during handling and processing.

Bags, big bags, containers, or transport silos are used for packaging and shipping. Information about the different methods of packaging and shipping is given in [229]. In Germany the general dust limit of 4 mg inhalable dust per cubic meter air must be adhered to when handling precipitated silicas. Similar regulations apply in other countries.

An easy incorporation of the silica into the rubber mixture and its good dispersion is crucial because it has a considerable effect on the process costs and on the rubber product performance. By selecting appropriate process parameters, it is possible to influence the surface properties and thus the reactivity of the silicas.

At present, a variety of manufacturers supply products that can be divided into the following three groups:

1) Products which can be described as "first-generation", "standard" or "conventional" silica.
2) Products belonging to the second generation of silica. Today, such products are frequently termed "easily dispersible silica" or "semi-highly dispersible (semi-HD) silica".
3) The third and newest generation of silica comprises a product group characterized by excellent dispersion. These products are described as "highly dispersible silica (HD silica)".

With regard to the group of "highly dispersible" silicas, it can be assumed that in addition to special precipitation parameters, only so-called short-retention driers (flash or spray

Figure 12. SEM pictures of different Precipitated Silicas

dryers) are used; while the use of long-retention driers (e.g. rotary driers) is typical for silicas of groups (1) and (2).

4.3.1.2. Physicochemical Properties

To characterize a silica means describing its (surface) structure, i.e. its morphology, as accurately as possible. This includes the ratio between the "inner" and "outer" surface, the size and shape of pores, the absorption capacity, the surface roughness, the primary particle size, the formation of aggregates from these primary particles with the development of siloxane bonds, and the combination of aggregates to form agglomerates held together by van der Waals forces. Other methods attempt to characterize the surface chemistry, i.e. they describe the number of silanol groups and their arrangement, surroundings, reactivity and the chemical composition and degradation behavior of the silica surface.

All synthetic *amorphous silicas* are white powders consisting of SiO_2 and between 2–10 wt% of physically adsorbed water. They are amorphous and no crystalline part can be detected. Depending on the production process amorphous silicas have tapped densities (DIN/ISO 787/XI) ranging from 50 g/L to 600 g/L. All amorphous silicas consist of primary particles, aggregates and agglomerates (DIN 53 206). During the production process, primary particles grow together to form chemically bonded aggregates. These aggregates then form agglomerates held together by van der Waals forces and hydrogen bonding. In powder form, only agglomerates exist. Primary particles can be identified as individual particles by means of suitable analytical methods (e.g. transition electron microscopy, TEM). Typically, these spherical primary particles have a diameter in the range of 2 – 20 nm [230]. Aggregates are assemblies of primary particles which are grown together in the form of chains or clusters. The aggregates are formed by the collision of particles, by particle growth and by the further deposition of silica onto these aggregates. In practice, the degree of aggregation defines the structure of the silica, because aggregates can not be broken into primary particles by any dispersion process. On the other hand, when dispersed in a fluid, agglomerates can be broken into aggregates. Typically, the mean particle sizes for agglomerates are between 2 and 250 µm for silicas in powder or microgranular form whereas granulated silicas have a mean particle size of up to 3000 µm.

One important method of characterization is the specific surface area, mainly measured by the Brunauer–Emmett–Teller (BET) method [231] or modernized versions of it [232]. The BET method always provides the sum of the so-called "outer, geometrical" and "inner" surface, i.e. the surface within the porous silica structure. If the value obtained for the surface using the BET method is compared to that from electron micrographs, which only indicate the outer surface, then it is at least possible to estimate the ratio of outer and inner surface. Evaluation of other sections of the BET isotherms provides additional information. The so-called "C value", calculated from the BET isotherms, gives a qualitative indication of the magnitude of the interaction between the surface of the silica and the adsorbed material and hence of the chemical reactivity of the surface [233]. If it is ensured that not only the surface of a sample is covered with nitrogen but also that the pores are filled, then the distribution of mesopores (pores between 2 and 30 nm in size) can also be determined using the Barett–Joyner–Halenda (BJH). The specific surface area of industrial precipitated silica varies widely from 30 m^2/g up to 700 m^2/g.

Another important parameter to describe precipitated silicas and silica gels is the porosity expressed by the pore size distribution. This parameter describes the sorption characteristics of the silica. However, it should be mentioned that the pore size distribution and the surface area are the results of an underlying parameter: the particle sizes of the aggregates.

According to IUPAC [234] the following classifications exist:

Micropores	pore diameter	0 – 2 nm
Mesopores	pore diameter	2 – 50 nm
Macropores	pore diameter	50 – 7500 nm

Precipitated silicas are typically macroporous materials. Here the mercury method is generally most suitable for the reliable determination of pore sizes above 30 nm. WASHBURN et al. [235] introduced the mercury in-

trusion method to measure the pore size of a porous silica.

Typically, precipitated silicas show a broad pore size distribution whereas silica gels exhibit a sharp maximum (Fig. 13). Usually, fumed silicas have only outer surface without any pores. The outer surface is easily accessible in adsorption or desorption processes.

Figure 13. Pore size distribution of a precipitated silica and a silica gel

Hydrophilic precipitated silicas contain between 2 - 10 wt% of physically adsorbed water, hydrophilic fumed silicas only up to 2%. After 2 h of drying in a drying cabinet at 105°C, the physically adsorbed water is removed. The weight difference before and after drying is equivalent to the mass of physically bonded water (method according to ISO 787/2, ASTM D 280) and is called loss on drying. The amount of chemically bonded water is determined by heating a sample for 2 h at 1000°C (loss on ignition, method according to ISO 3262/11, ASTM D 1208). The weight difference before and after heating at 1000°C is equivalent to the weight of physically bonded water (= loss on drying) plus the weight of chemically bonded water.

Generally, the pH value (ISO 787-9) of precipitated silicas is approx. 7, for hydrophilic fumed silica it is around pH 4.

The determination of the sieving residue (ISO 787/18) provides an indication of the difficulty to disperse amount of the fractions in a precipitated silica.

In industrially produced precipitated silicas besides SiO_2 as the main component, traces of other metal oxides, sulfates and chlorides can be determined. The SiO_2 content is determined gravimetrically by fuming off with hydrofluoric acid. The analysis for metal oxides is then performed by means of atomic absorption spectroscopy (AAS) from the residue remaining from the fuming off process. Sulfate and chloride contents can be determined by potentiometric titration.

The *Sears number* is a measure of the number of silanol groups on the surface and therefore a measure of the specific surface of a silica [236, 237]. The Sears number is equivalent to the quantity of 0.1 N NaOH required to titrate a suspension of silica from pH 6 to pH 9. The acidic silanol groups on the silica surface react with NaOH. The Sears number gives an indication of the number of reactive centers on the surface of a silica.

Figure 14. Decrease in pore volume of silica as pressure increases

The void volume [238], i.e. the silica structure as a function of the pressure, is considerably more reliable than the DBP (dibutyl phthalate absorption) number. In this method, the sample is subjected to a defined coarse crushing and then a specified quantity of the sample is transferred to a cylindrical glass chamber with a volume scale. The chamber is sealed by means of a moving piston. For the measurement, a constant pressure is applied to the piston until the volume of the sample in the chamber remains constant. Then the measured value is read off. Subsequently, the pressure exerted on the sample is increased again. Figure 14 shows

Figure 15. Different types of hydroxyl groups on silica surfaces

the decrease in structure (or the void volume) as the pressure increases. In this figure a new silica, prepared using a modified manufacturing method, is compared with the reference silicas Zeosil 1165 MP, Ultrasil 7000 GR and the conventional silica Ultrasil VN 3 GR with the same cetyltrimethylammonium bromide (CTAB) surface area (see below). It is obvious that the new products have a significantly higher void volume even at the start of the measurement. As the pressure is increased the pore volume decreases, yet always remains well above the level of the respective reference. In other words, the higher porous structure remains intact even when subjected to great stress, e.g. during mixing in a Banbury mixer. The more stable structure can be penetrated more easily by polymers and is indicative of a more advantageous mixing and processing behavior of the sample.

The CTAB method is known from the area of carbon black technology and also used in the case of silica. The method is based on the adsorption of the surface-active CTAB molecules from aqueous solutions [239]. The preferred adsorption site for these large CTAB molecules is the outer, geometrical surface, which correlates quite well with the surface area accessible for the rubber [240, 241]. Comparison with the BET surface, which is the sum of the outer and inner surface of a filler, provides an indication — with a certain margin of error — of the ratio between the inner surface and the total surface. The CTAB surface often coincides very closely with the surface determined from electron-microscopic images (TEM).

Typical physicochemical data of the different silicas are given in Table 5.

Surface Modification. Synthetic amorphous silicas (SAS) have two different functional groups on their surfaces: silanol (Si−OH) groups and siloxane (Si−O−Si) groups (Fig. 15). These two groups substantially influence the surface properties and hence the application properties. The fully hydroxylated surface of precipitated silica has ≈4.6 silanol groups per nm^2 [242 – 244] , for silica gels the value is about 5.5 [245] and for fumed silica ≈2.5 – 3.5 [246] which results in the hydrophilic character of the products.

Whereas the siloxane groups are generally chemically inert, the reactivity of the silanol groups allows chemical surface modification [247, 248]. Thus, the reaction with organosilanes [249 – 253], silicone fluids, or chlorosilanes [254 – 257] leads to hydrophobic silicas.

Hydrophobization is carried out industrially both by wet processes (e.g., addition of organochlorosilanes to the precipitate suspension) and dry processes (e.g. the reaction of fumed silica with dimethyldichlorsilane [258]). A scheme of the reaction and change in surface from hydrophilic to hydrophobic is shown in Figure 16.

In coating processes, in contrast, no chemical reaction takes place; the coating agents are physically adsorbed on the silica surface. Wax coating with wax emulsions has become industrially important [259].

Table 5. Physicochemical data of synthetic amorphous silica

			Precipitated silica	Silica gel	Pyrogenic silica

Figure 16. Reaction scheme of dimethydichlorosilane with the silica surface

Figure 17. Simplified silica–rubber coupling reaction with Si69® = bis-(triethoxy-silyl-propyl)-tetrasulfane

Since the early 1990s precipitated silica has been used as a high-performance reinforcing fillers in rubber compounds for passenger car tires. To achieve a higher reinforcement silane coupling agents are needed. They provide a chemical link between precipitated silica and rubber polymer [260 – 262] (see Fig. 17). Most used silane for this application is bis(triethoxysilylpropyl)tetrasulfane (e.g. Si69® from Degussa).

4.3.1.3. Commercial Products [263 – 266]

In the previous section, the silicas for the rubber-processing industry were classified according to their dispersion as "conventional", "semi-HD or easily dispersible" and "HD" silicas. This classification has gained acceptance in the literature and will also be adhered to in the following overview in Table 6 (based on the manufacturer's own classification). In Table 6 the products are also classified according to their specific surfaces (in this case CTAB surface). According

to ISO 5794 precipitated silicas can also be classified from A – F according to their BET surface area, with A for silicas with more than 191 m^2/g and F for those with less than 70 m^2/g.

Table 6. Classification of rubber silicas and silicates according to their CTAB surface area and dispersion

Dispersion	CTAB surface area / (m^2/g)		
	100 ± 20	160 ± 20	200 ± 20
Conventional	Ultrasil 360 (GR) Ultrasil AS 7 Ultrasil 880 Hubersil 1613 Hubersil 1633 Hubersil 1635 Hi-Sil 315 Zeosil 125 Gr Zeolex 23 Zeolex 80	Ultrasil VN3 (GR) Hubersil 1714 Hubersil 1715 Hubersil 1743 Hubersil 1745 Hi-Sil 210 Hi-Sil 233 Hi-Sil 255 Hi-Sil 243 LD Zeosil 145 Gr Zeosil 174 G Zeolex 25	Hi-Sil 185/195 Zeosil 195 Gr Hi-Sil 170

4.3.1.4. Essentials of Rubber Silicas

The oldest use for fine silicas and silicates was in shoe soles. Here, the high demands with regard to wear can be met with ease by such reinforced vulcanized materials. The great advantages of light-colored reinforcements as compared with carbon black is the possibility of satisfying practical, not to mention fashion-related requirements, whether they be that shoe soles be non-marking, transparent or a particular color, or whether it be necessary to stamp cable sheaths with colored lettering.

If the fineness and therefore the high specific surface of a substance is considered to be a main contributing factor to the reinforcing effect in rubber, then fine silicas and silicates must act similarly to rubber black. This is indeed the case, but clear distinctions must be made [267]. In simple terms, the cross-linking of rubber during vulcanization proceeds in a different manner in the presence of carbon black than in the presence of silica or silicates. The reasons for this are: adsorption of cure ingredients and the "immiscibility" of hydrophilic silica with the hydrophobic rubber. Consequently, silicas are mostly used in conjunction with bifunctional organosilanes, such as Si69®. Organosilanes undergo chemical bonding to the silica surface, thereby providing the potential for cross-linking to the rubber.

4.3.2. Inactive White Fillers

Inactive white fillers are preferably used as extenders to make compounds cheaper and to make processing easier. Since these fillers are natural products that are generally untreated, apart from possibly being ground up, the content of rubber poisons is especially important for product quality. The content of rubber poison should generally not exceed 10 ppm, based on the compound. The most important fillers in terms of quantity are calcium carbonate and kaolin.

Calcium carbonate [*471-34-1*] occurs naturally as chalk, limestone, and marble. All three forms can be used as fillers after appropriate processing (grinding, breaking up). The average particle diameter of these products is 2 – 100 µm. Calcium carbonates produced chemically by precipitation are characterized by greater particle fineness, with average particle sizes of 0.1 µm. The specific surface area can be up to 100 m^2/g. Precipitated chalk is therefore a semiactive filler. The differences in color and the effects on processibility, extrudability, and vulcanization of the products used in the rubber industry depend little on the purity and the particle size.

Kaolins [*14808-70-7*], [*14808-60-7*], [*1332-58-7*] are aluminum silicate hydrates. The rubber industry differentiates between soft and hard kaolins, according to the behavior of vulcanizates. Vulcanizates filled with hard kaolins are harder (i.e., hard kaolin has a smaller particle size and is therefore more active). Hard kaolins are suitable for stable injection compounds. The content of crystalline quartz in kaolins used in rubber is generally $<0.5\,\%$. *Calcined kaolins*

have a certain importance because of the good electrically insulating properties in vulcanizates. Besides kaolins, natural calcium or magnesium silicates are used. These products occur naturally as talc [*14807-96-6*], or wollastonite.

Silicon dioxide occurs naturally in both the crystalline and the amorphous forms. Crystalline silicon dioxide is used mostly in the form of ground quartz. Kieselguhr, silica, or diatomaceous earth are among the amorphous forms. *Neuburger Kieselerde* (trade name sillitin) has a particular structure. It consists of corpuscular quartz [*14808-60-7*] and laminar kaolinit [*1318-74-7*]. With a specific surface area of ca. 10 m^2/g, it belongs to the inactive fillers, but combines the special advantages of quartz (good extrusion, little residual deformation) with those of kaolin (facile blending) because of its particular structural properties. The MAK value is 0.15 mg/m^3 because of the crystalline quartz content.

Barium sulfate is occasionally used as a filler because of its high density. It is also thought to give some protection against nuclear radiation.

The zinc oxides found on the market are used mainly as activators for sulfur vulcanization. Only a very small proportion are actually used as fillers for highly elastic, very hard vulcanizates (e.g., for spring elements). The product used here is precipitated zinc oxide with a specific surface area of 30 – 50 m^2/g.

Aluminum hydroxide is used as a flame retarder (release of water) in EVM cable mixtures. Inactive and weakly active types are available, depending on the specific surface area.

4.3.3. Coating of Fillers

A range of processes for surface treatment (coating) has been developed to improve the properties of fillers. Through this coating, an inactive filler is occasionally converted into a semiactive one, without altering the particle size. Calcium carbonate, talc, and zinc oxide can be treated with *stearic acid* to improve distribution, and silicas, silicates, and kaolins with *silanes* to reduce the compound viscosity and to improve mechanical properties of the vulcanizate [121]. Silanes can also be added during the actual mixing process, with results similar to those obtained in filler pretreatment.

4.4. Pigments [122, 123]

(see also → Pigments, Inorganic; → Pigments, Organic)

Both organic and inorganic pigments can be used for coloring rubber compounds. Organic pigments are characterized by very high brightness and particularly attractive brilliance (purity of the tint), but they are inferior to inorganic pigments in their aging properties. The advantages of inorganic pigments are their excellent fastness and their resistance to chemical effects, heat, and weathering.

The preferred pigments for rubber compounds are products that do not contain any rubber poisons; do not impair vulcanization, other processing conditions, or the mechanical properties of the vulcanizate; and are toxicologically harmless. Pigments for the *rubber industry* are available commercially as powders in the pure form or in polymer-bound form. For use in *latex*, aqueous pastes with high pigment concentration or powdered products treated with a dispersion agent to ease dispersion in water are suitable.

4.4.1. White Pigments

(see also → Pigments, Inorganic, Chap. 2)

White pigments can be counted among the inactive fillers because of their particle size. Since high levels of white pigments can lead to a significant decrease in quality of the vulcanizate, they must have good whitening and high hiding power to have a sufficient effect in small quantities.

Lithopone (a mixed pigment produced from zinc sulfide and barium sulfate) is a white pigment with relatively low whitening power. The various types of *titanium dioxide* are better in this respect and are therefore among the most important white pigments in the rubber industry and elsewhere. Both titanium dioxide modifications, rutile and anatase, are suitable as rubber pigments. The rutile types have a ca. 25 % greater whitening and hiding power

than anatase, and are thus preferred on most cases. Rutile types, particularly the inorganically coated rutile pigments, also impart better weather resistance and lightfastness to vulcanizates. In shoe soles, up to 15 phr titanium dioxide is added; in roof sheeting, up to 50 phr. Because of the high price of titanium dioxide, it is partially replaced by zinc oxide or sodium aluminum silicates in low-value compounds.

4.4.2. Inorganic Colored Pigments
(see also → Pigments, Inorganic, Chap. 3)

To achieve muted red, brown, beige, and yellow tints, *iron oxide pigments* are particularly suitable. Since iron oxides often contain rubber poisons such as copper and manganese, they must be analyzed carefully for these impurities. In special pigments for the rubber industry the content of rubber poisons is limited by the producer.

To achieve muted green and yellow-green tints, *chromium oxide* pigments are mainly used. Here too, types that are almost free of rubber poisons are available for the rubber industry.

For blue coloration, *cobalt pigments* are used, as well as *ultramarine blue* with its color nuances of greenish blue to violet. It is favorably priced but has relatively weak color strength.

Cadmium and *chrome yellow* pigments have decreased in importance for ecological reasons. They were used principally because of their bright tints and brilliance.

All desired coloring effects can be obtained by mixing colored pigments. Inorganic colored pigments are inactive fillers because of their low specific surface area. However, they are always used in small quantities.

4.4.3. Organic Colored Pigments
(see also → Pigments, Organic)

Compared with inorganic pigments the organic ones have greater color strength and more brilliant tints, but are less lightfast.

Most often *azo pigments* are used, e.g., the coupling product from diazotized 2-chloroaniline with 3-methyl-1-(4-nitrophenyl)-5-pyrazolone, which is used for orange tones. Other types of compounds are occasionally used (e.g., *alizarin* derivatives). For blue and green tints, *phthalocyanines* are also suitable. On weathering, phthalocyanines lead to crazing on the vulcanizate surface. To achieve brilliant tints with good hiding power, inorganic pigments (hiding power) are used in combination with organic ones (brilliance).

4.5. Organic Fillers

Organic fillers can be divided into naturally occurring and synthetic products. However, determining whether the organic fillers should be regarded as real fillers or should be classified under other categories is often difficult.

Synthetic products, such as phenolic and styrene resins have a strong reinforcing effect, but their advantages with respect to the processing of the compound (plasticizing effect, flow properties) are often more apparent. They are therefore dealt with in more detail in Chapter 6 (processing aids).

Naturally occurring products include cellulose, lignin, and cork. In terms of quantity used, these products play a minor role in the rubber industry. As fibers or tissues, the boundary between real fillers and construction components of composite materials is flexible. Cork is often used in sealants. The very coarse particles can be considered as inactive fillers, or particularly in the case of seals, the rubber can be considered a binding matrix for cork particles.

5. Plasticizers

5.1. General

Plasticizers are the most important chemicals after fillers, in terms of quantity, for the production of rubber compounds. Reasons for their use in rubber compounds and vulcanizates include:

1) Improvement of the processibility by targeted adjustment of compound viscosity
2) Lowering of the elastomer content by high filler and plasticizer level, thus lowering the price of the compound
3) Improvement of filler distribution
4) Changing the vulcanizate properties (e.g., improvement of low-temperature flexibility, elasticity, and extendability)

Plasticizers that bring about an improvement in flow properties and processibility are frequently known as *processing oils*. Products that are used to extend and therefore lower the price of compounds are called *extender oils.*

The plasticizer functions mentioned are generally not fulfilled by any single product.

Apart from these tasks, a plasticizer must meet the following conditions:

1) Compatibility with the particular polymer
2) No interactions with the cross-linking system
3) Little or no volatility at the vulcanization temperature
4) No harmful toxicological properties

Depending on the application of the vulcanizate, the extractability of the plasticizer, staining in light, and contact staining (e.g., with varnish or textiles) must be considered.

Since, in principle, every compounding ingredient that is liquid at the processing temperature can act as a plasticizer, a broad spectrum of substances is sold to the rubber industry as plasticizers. The boundary between plasticizers and processing aids (products that improve processing of the mixture but do not actually exhibit plasticizing action) is flexible.

The theory of plasticizer action [124] differentiates between real and pseudo, or primary and secondary plasticizers. *Primary plasticizers* dissolve or swell the polymer and thus increase the mobility of chain segments. This decreases the viscosity of the unvulcanized compound, and the vulcanizate has lower hardness, improved elasticity, and in general a lower solidification point.

Secondary plasticizers hardly dissolve the polymer, or not at all, and act as a lubricant between the molecular chains of the rubber. They improve the moldability of the compound, without markedly changing its viscosity. Examples are waxes and fatty acids.

No sharp boundary exists between primary and secondary plasticizers. The classification of plasticizers into each group depends on their chemical structure and the nature of the rubber (compatibility).

Plasticizers can be classified as natural products, mineral oils, and synthetic plasticizers. Reasonably priced mineral oils are used mainly as extenders. The choice depends primarily on compatibility and price. The relatively expensive synthetic plasticizers, which are often also PVC plasticizers, are used to improve low-temperature properties. With polar rubbers (e.g., NBR) an improvement of low-temperature properties cannot be achieved with mineral oil because of insufficient compatibility.

5.2. Mineral Oils

Mineral oils constitute by far the most important group of plasticizers in terms of quantity. They are reasonably priced and are known as processing or extender oils for many rubber compounds, depending on their use [124, 125].

Mineral oil plasticizers are divided into various subgroups characterized by the relative percentages of paraffinic, naphthenic, and aromatic carbon atoms. To differentiate among the large number of products of widely differing origin and composition that are available to the rubber industry, differences from mineral oil analysis are used, which permit adequate characterization and classification. Classification by the viscosity – gravity constant (VGC) has now become widely used. This constant is determined according to DIN 51 378 (→ Lubricants and Lubrication). The connection between VGC range and mineral oil types is given below:

Paraffinic	0.790 – 0.819
Relatively naphthenic	0.820 – 0.849
Naphthenic	0.850 – 0.899
Relatively aromatic	0.900 – 0.939
Aromatic	0.940 – 0.999
Highly aromatic	1.000 and higher

Table 7. Properties of different types of mineral oil

Property	Mineral oil		
	Paraffinic	Naphthenic	Aromatic
Density	low	→	high
Color	light	→	dark
Refractive index	low	→	high
VGC	low	→	high
Viscosity	low	→	high
Aniline point	high	→	low

Determination of the carbon distribution in mineral oils was first standardized with ASTM D 2140. The method described in DIN 51 378 follows this standard and can be used to determine carbon distribution via the VGC and the refraction intercept (r_i). The statistical distribution of carbon atoms in paraffinic (C_P), naphthenic

Table 8. General polymer – mineral oil compatibilities

Mineral oil type	Type of rubber according to DIN ISO 1629 *								
	NR	IR	SBR	BR	NBR	CR	CSM	EPDM	IIR
Paraffinic	+	+	+	+	–	–	–	+	+
Relatively naphthenic	+	+	+	+	–	–	–	+	+
Naphthenic	+	+	+	+	–	0	0	+	0
Relatively aromatic	+	+	+	+	0	+	+	0	–
Aromatic	+	+	+	+	+ *	+	+	0	–
High aromatic	+	+	+	+	+ **	+	+	0	–

* + = compatible; 0 = compatible under certain conditions; – = incompatible.
** Low dosage.

(C_N), and aromatic (C_A) bonds is obtained as a percentage.

By knowing the constitution, the general properties (see Table 7) and compatibility of mineral oils with various rubber grades can be derived (Table 8).

The quantities of mineral oil added to rubber compounds are generally between ca. 5 and 50 %; low dosages are added when used as processing aids, and higher dosages for extending. Even higher dosages (>50 %) are used in EPDM compounds. For certain applications, this rubber is cross-linked with peroxide instead of sulfur. In this case, paraffinic mineral oils are preferred in order to exclude interactions with the cross-linking agent.

The largest quantity of mineral oil plasticizers is used in the tire industry to produce compounds based on NR, IR, SBR, and BR. Although these polymers are readily compatible with all types of mineral oils, aromatic oils are used predominantly for tire production.

A considerable quantity of mineral oil is already added to synthetic rubber during production (oil-extended polymers).

Toxicology and Occupational Health. The effects of mineral oils on health are increasingly under discussion [126 – 128] because these oils may contain polycyclic aromatic hydrocarbons, some of which are known to be carcinogenic [129]. Such oils must be labeled according to EC guidelines [130] and OSHA regulations. The OSHA regulations are based on the classification of the International Agency for Research on Cancer (IARC) [131].

On the part of the mineral oil industry, these health considerations have led to the development and production of products which are less harmful [127].

5.3. Synthetic Plasticizers

Because of their much higher prices, the quantity of synthetic plasticizers used in the rubber industry is much lower than that of mineral oils. However, they are indispensable for achieving special vulcanizate properties, in particular for polar rubber grades (NBR, CR, EVM), because these grades are not or only partly compatible with mineral oil plasticizers. Synthetic plasticizers are used because they improve the low-temperature flexibility of vulcanizates. Many different products with greatly differing types of action are commercially available (e.g., ethers, thioethers, esters, and thioesters). Some of these plasticizers are used for thermoplastics, in particular PVC.

The incorporation of synthetic plasticizers can be carried out both by mill mixing and in internal mixers. Plasticizers make the incorporation and dispersion of fillers much easier and simultaneously lower compound viscosity. Plasticized compounds very often exhibit increased building tack. Processing of the compound (extrusion, calendering, injection molding) is generally improved. In the case of vulcanizates, depending on the dosage, a lowering of the Shore hardness and generally a decrease in strength with a simultaneous increase in elongation at break are achieved.

The low-temperature flexibility is considerably improved, in particular by ether and ester plasticizers. However, certain plasticizers have a marked volatility at elevated ambient temperature [132 – 134]. In particular, low molar mass ethers, which give outstanding improvement in the low-temperature flexibility of NBR, are quite volatile at the high temperature of use (in cars). Correspondingly plasticized articles lose their

low-temperature flexibility and harden as a function of time and temperature. Ether – thioether plasticizers are much more satisfactory in this regard [135].

A careful choice must also be made to achieve good or, in individual cases, improved hot-air resistance. Plasticizers with high volatility are definitely unsuitable. However, the use of high molar mass plasticizers with very low volatility (e.g., polyesters or polyadipates) is questionable. They behave favorably with regard to hot-air aging but are less effective with respect to improving low-temperature flexibility.

Polychloroprene constitutes a special case. Synthetic plasticizers improve the low-temperature flexibility of this rubber as expected, but they do not suppress the crystallization tendency [136]. In addition to other compounding measures, aromatic mineral oils should be used in this case [137].

Although synthetic plasticizers show particularly good compatibility with polar rubber grades, only a limited level can be applied depending on the type of polymer, polarity of the plasticizer, and general compounding formulation. Therefore, general dosage limits cannot be given. Dosages of more than 40 phr can be used in only a few cases. The most frequently used dosages of synthetic plasticizers are between 5 and 20 phr.

The different chemical groups of synthetic plasticizers are described below.

Ethers, such as dibenzyl ether or the formaldehyde acetal of diethylene glycol monobutyl ether (BCF), lead to very good low-temperature flexibility in NBR vulcanizates, but have limited use because of their volatility.

Ether – thioethers (e.g., condensation products based on thiodiglycol and alcohols) are very effective plasticizers for improving the low-temperature flexibility of NBR and CR vulcanizates. They are considerably less volatile than monomeric ethers and, in particular, improve the hot-air aging resistance of, for example, NBR vulcanizates [135].

Esters are the most important synthetic plasticizers in terms of quantity. Examples are phthalates [e.g., 2-ethylhexyl phthalate (DOP)], adipates [e.g., dioctyl adipate (DOA)], sebacates [e.g., dioctyl sebacate (DOS)], phosphates [e.g., tricresyl phosphate (TCF)], and trimellitates.

While *DOP* has proved to be a reasonably priced plasticizer with average effectiveness for improving the low-temperature flexibility of NBR and CR vulcanizates, *DOS* has an outstanding effect on CR vulcanizates. Phosphate esters are used to improve flame resistance, and *trimellitates* have been shown to be particularly suitable for HNBR.

Thioesters also have a certain importance, in particular butyl esters of methylenebisthioglycolic acid, which give NBR vulcanizates very good low-temperature flexibility and high elasticity. Also *phenol alkylsulfonates*, which are principally known as PVC plasticizers, are used for NBR and CR because of their low price. Their ability to improve low-temperature flexibility lies between that of polyesters and DOP.

Polyester Plasticizers. Besides monomeric esters, polyester plasticizers (i.e., esters based on adipic and phthalic acids, and propane- and butanediols) are also used. They are relatively nonvolatile and therefore used for high-temperature vulcanization (e.g., UHF processes) and for articles that are exposed to high ambient temperatures. The disadvantage of polyesters is a comparatively small improvement in the low-temperature flexibility of vulcanizates.

Chlorinated paraffins with a chlorine content up to 70 % are used in dosages up to ca. 20 % to decrease the flammability of rubber articles. They are liquid-to-viscous substances and are used mostly in combination with antimony trioxide.

The importance of chloroparaffins for the rubber industry is relatively slight and will decrease even further. In some areas (e.g., the cable industry), aluminum oxide hydrate, magnesium hydroxide, and zinc borate have been established as alternatives to these highly chlorinated compounds.

Outlook. Various possible solutions to the problem of the extraction of plasticizers by fats or oils from finished products (e.g., bellows for universal joints) have been discussed. Polymeric plasticizers (e.g., polyesters) are better than monomeric ones in this respect, but

their improvement of low-temperature flexibility is insufficient. The use of reactive plasticizers has been investigated [136]. These compounds should become bonded to the hydrocarbon chain of the polymer during vulcanization. However, the fixing of these reactive plasticizers (e.g., ethylene glycol dimethacrylate or compounds containing vinyl groups) to the polymer backbone occurs only in unsatisfactory yield or has a considerable effect on the actual cross-linking of the polymer. A practicable solution has not been found.

5.4. Natural Products

A range of natural products are used because of local availability or to achieve particular effects. However, they are of little importance in terms of quantity. These products are oils, waxes, and poorly defined high molar mass products of animal and paraffinic origin, such as lanolin, palm oil, soybean oil, linseed oil, animal gelatin, pine tar, and rosin.

In the usual relatively low dosages, these products act mainly as lubricants (in the case of fatty acids), rather than plasticizers, or are used to improve building tack (rosin).

6. Processing Additives

6.1. Behavior and Classification of Processing Additives

Processing additives are defined as materials used at relatively low dosage levels, that improve processing characteristics of rubbers without significantly affecting their physical properties [204]. The action of processing aids can be physical and/or chemical, depending on their chemical structure, the processing conditions, and the rubber system that they are used in.

Rubber processing is a multiple-step operation, depending on the polymer composition, type and level of filler, the curing system, and shaping and properties of the finished rubber article. A wide range of viscosities, polarities, temperatures, and shear rates has to be handled, often creating specific problems. Inhomogeneous polymer blends, poor filler dispersion, stickiness on machinery, low building tack, bloom, surface failures, and mold fouling are quite common.

Processing additives are often classified by their main function, but some of them are truly multifunctional.

Following the production steps of a rubber compound, the main problems to be solved are:

Viscosity reduction of natural rubber is achieved by *peptizers*, which cleave the long rubber chains and thus enable filler incorporation and blending with synthetic polymers.
Polymer blending is improved by *homogenizers* which control the domain size of the dispersed phase. Some homogenizers also act as filler dispersants and tackifiers.
Dispersing agents improve the incorporation of fillers and reduce the viscosity of the compounds.
Lubricants or *flow improvers* show their full performance mainly in high shear processes such as extrusion and injection molding. They improve productivity and surface quality of the finished article.
Tackifiers enhance the building tack of rubber parts, e.g., in tires or other rubber goods assembled from various compounds.
Some special *resins* are used to increase the hardness of rubber compounds while maintaining good processibility.
Release agents facilitate the demolding of the cured rubber parts. They also improve the filling of the cavity and reduce mold fouling (deposit on the molds).

Table 9 gives an overview on the classification of processing additives according to their effects.

6.2. Peptizers

Although the production of natural rubber with controlled viscosity (CV-grades) is gradually growing, the majority of NR needs viscosity reduction prior to blending with other polymers and/or filler incorporation. This is achieved by chemical peptizers, highly efficient combinations of organic iron complexes and an aromatic sulfur compound.

Table 9. Types and chemical composition of processing additives

Type of processing additive	Chemical composition
Peptizers	2,2′-dibenzamido-diphenyldisulfide
	zinc soaps
Homogenizers	resin blends
Dispersing agents	fatty acid esters
	metallic soaps
	fatty acids
	fatty alcohols
Lubricants	metallic soaps
	fatty acid amides
	fatty acids esters
Tackifiers	phenolic resins
	hydrocarbon resins
	coumarone resins
Reinforcing agents	phenolic resins
	polymer resins
Release agents	cross-linkable resins
	polyesters
	polyethers
	silicone oil emulsions

For many years the preferred peptizer was pentachlorothiophenol (PCTP) or its zinc salt. Meanwhile PCTP is banned in most parts of the world because it forms several teratogenic decomposition products. PTCP is replaced by 2,2′-dibenzamidodiphenyldisulfide (DBD) which is less toxic and reacts similarly.

The viscosity reduction of NR is achieved by two different mechanisms. When mixing on a roll mill or in an internal mixer, mechanical shear force is applied to polymer chains. When a chain is ruptured, free radicals are formed at both chain ends. Those radicals can recombine or react with neighboring NR chains, resulting in long chain branching. The radicals can also react with atmospheric oxygen, which stabilizes the radicals intermediately. The overall effect of this mechanical degradation of the molecular chains, so- called mastication, is low.

DBD reacts with free radicals to form stable compounds that do not react with other polymer chains. Thus the molar mass of the polymer is reduced efficiently, because mainly long chains are attacked by mechanical forces when mixing at low temperatures.

On *open mills* maximum temperatures of 80 – 90 °C are achieved, thus mechanical breakdown and stabilization by DBD is the main mechanism. Beyond 100 °C the viscosity of the NR is reduced so much that mechanical rupture of the chains is minimized.

Most of the NR in industrialized countries is processed in internal mixers. During the mixing cycle much higher temperatures are generated. From 120 °C and above oxidative chain scission is the dominant process, catalyzed by organic iron complexes, so-called boosters. This process is quite efficient, but the purely random attack on both long and short chains results in a strong increase of very short-chain material [205] which tends to stick on machinery and give unfavorable dynamic properties.

Figure 18 shows the molar mass distribution curves (measured by gel permeation chromatography) of untreated NR, the effect of mechanical mastication, and the action of two chemical peptizers. Mechanical mastication reduces the highest molar mass material, and some shorter chains are obtained. Both chemical peptizers act much more aggressively, the maximum peak at a molar mass of about 100 000 is sharply reduced, and much more short chain material is observed. In the case of untreated NR one should keep in mind that the highest molecular material, the so-called gel, is not even detected by gel chromatography. The gel content of the raw NR was 23 %, dropping to 2–5 % when mechanically treated with our without peptizers [205].

Iron complexes in use are mainly (1) iron phthalocyanine (Fe-Pc) and (2) iron hemiporphyrazine (Fe-Hemi). Their activities are comparable. The dosage of iron complexes in the peptizers is rather low, typically 0.1 – 1 wt%. Peptizers are used in dosages of 0.1 – 1 %.

The peptizers described here were originally designed to be used in a separate mastication step to utilize their full activity. For productivity reasons the mastication is now carried out as part of master batch mixing, namely in the tire industry. NR and the peptizer are blended in internal mixers for ca. 30 s, followed by addition of other polymers and fillers. After such a short time the temperature is still rather low. Thus, the iron complex does not work properly but is deactivated immediately by reaction with the carbon black. For this mixing procedure new peptizer concepts have been developed. The radical scavenging action of DBD is combined with the lubricating effect of metallic soaps. This material also acts as a flow improver and reversion inhibitor and thus is a truly multifunctional additive [206].

6.3. Dispersing Agents and Lubricants

This group contains the most important processing additives which are widely used to enhance the productivity of rubber mixing and shaping. The relation between chemical structure and main effects is described in Table 9, but most additives have more than one effect. So a clear discrimination is not always possible. Overviews are given in [204, 207, 208].

Dispersing agents and lubricants are mainly based on fatty acid derivatives such as esters, amides, and soaps. Their action depends on their polarity relative to the matrix that they are used in.

Fatty acid esters facilitate "wetting" of the filler surface, thus the filler incorporation is accelerated. The esters are low-melting materials suitable for the use on roll mills and in internal mixers. Stearates of pentaerythritol are commonly used. Because they are fully saturated compounds, they are thermally stable and have little influence on peroxide cure.

Combinations of *fatty acid amides* and *metallic soaps* are also popular. In most polymer systems they result in a good flow improvement. Due to their limited solubility in many polymers they can also act as internal release agents for molding.

Zinc soaps are the classical flow improvers, their effect is most pronounced in high-shear processes such as extrusion and injection molding. The soaps employed normally contain a number of double bonds in their carbon backbone to avoid a too high melting point which could result in dispersing problems. On the other hand the unsaturation limits their use in peroxide cured systems. Zinc soaps of higher molecular fatty acids (<C12) are able to form spherical or lamellar micelles. This behavior is believed to be the reason for their lower apparent viscosity under shear. Layers of soap micelles located between molecule chains can slide easily on each other, because the van der Waals forces between layers of micelles are weaker than the friction between rubber chains [204].

Since 2001 zinc-containing rubber chemicals are under scrutiny, especially in the EU, because of potential environmental problems (aquatic animal toxicity). Meanwhile first alternatives to zinc soaps with equal or better performance have been introduced [209]. Most efficient is a combination of alkali soaps and fatty acid esters. Due to their activating effect on sulfur cure they even open the opportunity to reduce the level of zinc oxide to a minimum.

For high tech applications which require low dosages and a high thermal stability *organosilicones* are available [204]. These condensation products of fatty acid derivatives and silicones provide excellent lubrication and good compatibility with rubber. Dosages as low as 0.5–1 phr can be sufficient, while conventional dispersing agents and lubricants require 2–5 phr, depending on the polymer system and especially the filler level.

Producers and Trade Names. D.O.G. Deutsche Ölgesellschaft, Germany (Deoflow), Kettlitz Chemie, Germany (Dispergator), Rhein Chemie, Germany (Aktiplast), Schill+Seilacher, Germany (Struktol).

6.4. Homogenizers

The most widely used homogenizers, sometimes also called *compatibilizers*, are resin blends. Homogenizers are designed to mix rubbers with different chemical composition, viscosity, and polarity. Homogenizers act by influencing the domain size of the dispersed polymer particles in the matrix of the continuous phase [208]. Thus, some ultimate properties such as tensile strength and elongation at break are improved, but also modulus values and abrasion resistance are increased, because homogenizing resins also enhance the filler dispersion. Often they also improve the tack of an uncured compound.

Homogenizing resin blends, once softened or melted, readily disperse in most elastomers, but they act at the interface of the polymer particles. Due to their adhesive properties they help to compact the batches. Thus higher shear forces can be applied at relatively low temperatures when the viscosities are still high. Normally mixing times are shortened but mixing energies are not necessarily reduced. In homopolymers homogenizers show the well-known and widely used effect of enhanced cured adhesion between bromobutyl innerliners (containing a resinous homogenizer in 3 – 8 phr) and the carcass compound of tubeless radial tires.

The most efficient homogenizers are rather high-molecular materials. As they are dark colored, they cannot be used in light colored compounds, but good homogenizers are available for this purpose, too.

Producers and Trade Names. Flow Polymer, USA (Promix), Rhein Chemie, Germany (Rhenosin), Schill + Seilacher, Germany (Struktol).

6.5. Tackifiers

In rubber technology tackiness means the ability of two uncured rubber compounds to stick together under moderate pressure. Moderate-pressure processes are used in the assembling of tires and tire retreading, of air springs, hoses, multicolored shoe soles, belts and profiles, to name a few. Normally building processes are carried out at ambient temperature, but sometimes also tack at elevated temperatures is required, e.g., in extrusion of reinforced hoses.

Natural rubber normally has sufficient tack because of its content of low-molecular materials, such as fatty acids, resins, and proteins. Synthetic rubbers, such as SBR or BR,however, often show a lack of tackiness.

Depending on the compound and the production conditions, short- or long-term tack might be required. On the other hand, tackifiers should not increase the stickiness to rubber machinery or give a sticky surface of the vulcanized article. Also the influence on the cure characteristics of the compound should be negligible.

The most popular resins used as tackifiers are hydrocarbon resins (C_5 or C_9 based), *p*-substituted phenolic novolaks and a specialty resin made from *p-tert*-butylphenol and acetylene which gives good long term tack [210, 211]. Hydrocarbon resins are relatively inexpensive and give good short-term tack, up to 3–4 days. After this period the tack drops sharply. Phenolic resins have a higher price but can be applied at lower dosages and have a better long-term tack. Their initial tack is similar to that of hydrocarbon resins. If extreme long-term tack is required, like in classical retreading, the butylphenol-acetylene resin is the material of choice. Good tack levels for up to four weeks can be achieved.

Producers and Trade Names. BASF, Germany (Koresin), CECA, France (Ribetak), Exxon, France (Escorez), Kolon, Korea (KC, KNR), Schenectady, USA (SMD), Schill + Seilacher, Germany (Struktol), Sumimoto Bakelite, Japan (Tackirol).

6.6. Release Agents

Release agents are important auxiliaries in the production of rubber parts. Because of the high tackiness of NR and many synthetic rubbers and

the uncured compounds made thereof and because of the tendency of hot cured rubber to adhere to the molding equipment, an economical production of rubber parts is only possible when using release agents, although in principle it is possible to design production processes without use of them.

6.6.1. Batch-Off Release Agents

Rubber compounds are typically mixed in a batch process with at least two (masterbatch and final mix) steps. After each step the compound is given a form (sheets, granules, feeding strips) and cooled, typically in a watery cooling bath. To prevent the formed compound from sticking together to one big lump batch-off release agents are applied, normally simply by addition to the water of the cooling bath. Apart from their release properties batch-off release agents must in some applications also provide anti-slip properties to prevent piles of sheeted rubber compound from slipping during handling and transport.

Blends of metallic soaps of fatty acids, inorganic fillers (silicates, mica), dispersing agents and surface active substances are commonly used in this application.

Producers and Trade Names. Hans W. Barbe, Germany (Promol), Rheinchemie, Germany (Rhenodiv), Kettlitz, Germany, Schill + Seilacher, Germany (Struktol).

6.6.2. Mold Release Agents

Mold release agents are necessary in the rubber curing process to prevent the cured article from sticking to the mold. Rubber, like many other polymers, has quite a low surface energy compared to the metal of a typical mold, leading to quite strong adhesive forces between the rubber and the mold, especially at elevated temperatures. Additionally, many rubbers have low tear strength at high temperatures. Therefore, on mold opening so-called 'hot tear' can occur.

Sacrificial Mold Release Agents. These are simple release agents that are applied to the mold before every curing cycle. In the past all kinds of *oils* and *waxes* and solutions and emulsions made from these have been used for this purpose and are still in use today for some applications. The drawbacks of these materials are insufficient release, uptake by the rubber compound, thus changing its physical properties and a severe mold fouling.

Another class of materials are the *silicone oils* or *silicone oil emulsions* (sometimes also called *silicone fluids*). These silicone oils exhibit superior release properties at very low dosages but unfortunately also show severe drawbacks: If the silicone oil is incorporated into the compound this leads to flow faults and poor knitting. The silicone oils transfer to the rubber part and prevent effective down-line processing like printing and adhesion. Silicone oil emulsions cause severe mold fouling [212].

The automotive industry has widely banned the use of silicone oils as release agents for automotive rubber parts because the silicone oils that are transferred from the mold to the rubber article later migrate to the car body and this creates massive problems in repainting operations.

Producers and trade names for silicone oil emulsions: Bayer, Germany (Levaform), Wacker, Germany, Dow Corning, USA, Schill + Seilacher, Germany (Struksilon).

Semipermanent Mold Release Agents. State of the art in mold release agents are the semipermanent systems, available both as solvent- or water-based systems. These agents consist of mixtures of reactive prepolymers that are applied to hot molds and there cross-link to form a polymeric coating. This coating levels the surface of the, on a microscopic scale, rough metal, thereby reducing the effective surface area, and also reduces the surface energy of the mold. These two effects synergistically lower the adhesion of the cured rubber and give good release properties [213].

The semipermanent coatings withstand multiple molding cycles, typically 30 to 50, but even up to a 100 cycles are possible, greatly depending on the individual rubber compound and the processing parameters.

Semipermanent release agents eliminate the drawbacks of the sacrificial mold release agents and additionally greatly reduce the buildup of mold fouling, giving considerable savings in cleaning costs and thereby greatly enhancing the profitability of molding operations [214].

Producers and Trade Names. Chemtrend (Monocoat), Franklynn, Henkel Loctite, Germany (Aqualine), Schill + Seilacher, Germany (Permalease).

Other Mold Coatings. Many different mold coatings (like chromium plating, PTFE coating, ceramic coatings, etc.) have in the past been tested to eliminate the need for release agents but only with very limited success. Either the release properties are not good enough (chromium plating) or the coatings do not last long enough to be cost effective (PTFE and ceramic coatings).

6.6.3. Release Agents for Special Applications

Apart from the very widely used batch-off and mold release agents there are a number of applications in the rubber industry that have triggered development of special release agents for, in part, very specific requirements.

6.6.3.1. Mandrel Release Agents

Rubber hoses are normally cured in autoclaves on so-called mandrels, typically metal or plastic parts that fill the inside of the hose and have to be removed after vulcanization. The hoses can be divided into long hoses which are straight and are normally extruded directly onto the mandrel, and shaped hoses which are extruded and reinforced without mandrel, cut to lengths, and then pushed onto a shaped mandrel.

Long-hose mandrel release agents consist of blends of surfactants and lubricating materials, sometimes silicone oil emulsions are used.

Producers and trade names : Rheinchemie, Germany (Rhenodiv), Degussa, Germany (Getren).

Mandrel release agents for shaped hoses need to have, in addition to the releasing power, a very high lubricity to reduce the friction forces when the uncured hose is pushed onto the mandrel and especially when removing the cured hose from the shaped mandrel.

Materials mainly used are water-soluble polyesters and blends of polyglycols and surfactants. The polyesters have the added benefit of being readily biodegradable.

Producers and trade names : Degussa, Germany (Getren), Schill + Seilacher, Germany (Struktol MR), Rheinchemie, Germany (Rhenodiv), Marbo, Italy.

6.6.3.2. Bladder Release Agents

Especially tires but also other hollow rubber goods are produced with bladders of butyl rubber that are inserted into the hollow and inflated good to provide the necessary pressure for the vulcanization process. To prevent these bladders from sticking to the inside of the rubber part they are coated with bladder release agents which last for a number of curing cycles. Special blends of reactive silicone resins and lubricants are used in this application.

Producers and Trade Names. Chemtrend, USA, Rhodia, France (Lyndcoat).

6.6.3.3. Inside Tire Paint

Other producers rely on inside tire paints for the release of the bladder from the tire inner liner. These paints are sprayed onto the inside of every tire before mounting it to the press. The inside tire paints consist of blends of surfactants, lubricating agents, inorganic fillers (silicates, mica, carbon blacks) and dispersing agents, typically nowadays based on water as a solvent.

Producers and Trade Names. Chemtrend, USA, (Monocoat), Rheinchemie, Germany, (Rhenodiv), Schill + Seilacher, Germany (Struktol LR).

6.6.3.4. Outside Tire Paints

As with the inside tire paints some producers rely on outside tire paints rather than on mold release agents for their tire molds. These outside paints are also applied to every tire and are of similar makeup as the inside paints, of course this time optimized for release at the tire-mold interface. Producers are the same as for inside tire paints.

6.7. Other Processing Additives

A variety of resinous materials have been in use since the beginning of rubber technology. Natural resins such as *gum rosin* lose importance, mainly because of inconsistent quality and difficult handling.

High styrene-butadiene resins are used to achieve high hardness combined with good processing ability, e.g., in the bead/apex area of radial tires. Styrene levels of 85 % in the copolymer are quite common, while polystyrene itself is incompatible and too high-melting to be incorporated into a rubber matrix.

Factice is a traditional processing additive, made from rapeseed oil or soybean oil by heating with sulfur. It was used much in combination with CR in weather strips, but in this application CR has been replaced by EPDM (without factice). A small amount of *white factice*, made from rapeseed oil cross-linked with disulfur dichloride is used as a softener in erasers. Most traditional factice producers have stopped production.

Sometimes also *mineral oils* are summarized under processing additives, but they only have a softening effect and require relatively high dosages.

Pine tar has also been used for many years, in some applications it improves adhesion but has a strong smell.

Asphalt and *bitumen* (→ Asphalt and Bitumen) are cheap additives for dark rubber compounds. Often an oxidized material called *blown bitumen* is in use, also called *mineral rubber*.

7. Rubber Adhesion

The adhesion of rubber to inelastic materials covers two completely different aspects; the adhesion of rubber to steel cords or textile reinforcing materials, and its adhesion to flat metal surfaces. They differ so sharply in application, technology, and chemistry that they are dealt with separately.

7.1. Adhesion of Rubber to Reinforcing Materials

Rubber articles, such as tires, conveyor belts, driving belts, and hosing, have a common feature; during use they are subjected to periodic extension forces of differing strength, which severely limit the lifetime of the elastic materials. For this reason, these articles are built up as a composite of rubber and reinforcing materials. The elastomer matrix is characterized by high elasticity and low tenacity, while the solid matrix has high tenacity and dimensional stability, but low extendability. The strength of the bonds between the two different materials is decisive for the technical usability of the articles mentioned. Different systems are used to improve the bonding, which depend on the nature of the materials employed.

Rubber Matrix. Sulfur- cross-linked rubbers generally show a considerably higher bonding tendency than polymers with saturated main chains. Within the group of sulfur- cross-linkable rubbers, polar rubbers such as CR and NBR are more readily bonded to the reinforcing materials than nonpolar rubbers such as NR, BR, SBR, and EPDM.

Solid Matrix.

Organic reinforcing materials also differ in their bonding tendency. *Cotton* exhibits a very high tendency to bond to rubber. However, cotton fibers have rarely been used except in the Third World since the 1960s. Until the 1940s, no other reinforcing material was available, but with the advent of rayon, nylon, and polyester, cotton rapidly lost its importance as a technical yarn for rubber applications because of its structure. Being a staple fiber, cotton is clearly weaker than the *man-made fibers* rayon, nylon, and polyester, which are processed as monofilaments in the industrial fiber sector. All commercially important composite materials are built up using these carriers. If particular properties with regard to shrinkage, toughness, modulus, and resistance to chemicals are required, special fibers such as aramid fiber or spun polyethylene are used. Of the man-made fibers, rayon exhibits the greatest adhesion tendency toward rubber, whereas nylon and polyester bond much less strongly because of their chemical structure and morphology.

Inorganic Fibers. Steel cord plays a major role among the inorganic fibers. To improve corrosion behavior and adhesion to rubber, steel cord is usually processed with a brass- or zinc-coated surface. Brass- coated steel cord was incorporated into tire technology through radial tires, which were introduced in the 1960s by Michelin and represent the current state of the art. *Glass fiber* is used in speciality areas such as timing belts.

Various systems can be used to improve *adhesion* between reinforcing carriers and rubber, particularly after aging. These are described below.

RFL-Dip [176 – 179]. Adhesion promoters based on resorcinol – formaldehyde resins in combination with sulfur- cross-linkable latices have been known for impregnating textiles since 1935 [RFL-dip = **r**esorcinol (producers are, e.g., Koppers, Sumitomo Chemical), **f**ormaldehyde, **l**atex (producers are, e.g., BASF, Bayer, Du Pont, Enichem, Hoechst)]. RFL-dip is an aqueous dispersion of resorcinol, formaldehyde solution, and rubber latex. Its solid content depends on the absorption capacity of the textile to be impregnated, and is between 10 and 30 %. The absorption capacity of the textile depends directly on the ratio of amorphous to crystalline parts in the fiber. The higher the crystalline portion, the higher should the solid material content of the RFL-dip be. The textile is passed through this dispersion and predried. In a subsequent step, resorcinol is condensed with formaldehyde at 160 – 220 °C to form a resin. This results in strong mechanical and chemical interactions between the resin and the textile. If the reinforcing material thus impregnated is combined with an unvulcanized rubber compound, sulfur and accelerators from the rubber compound diffuse into the dried latex particles. These are in intimate contact with the resorcinol – formaldehyde resin and are cross-linked with the rubber during subsequent vulcanization. Heat-stable and flexible bonds are built up among the solid carrier, the resin, the latex, and the rubber by this process.

The nature of the latex used depends strongly on the nature of the rubber. For NBR, the best adhesion is achieved by using NBR latex. For NR, SBR, and CR, the use of VP-latex, a terpolymer of styrene (25 – 27 %), butadiene (60 – 63 %), and vinylpyridine (10 – 15 %) is recommended.

Rayon and nylon can be impregnated in this way. *Polyester*, *aramid*, and *glass fiber* must be pretreated first since, because of different reasons, such as high steric hindrance or a high degree of crystallinity, chemical interaction with the resin is not possible or occurs to an insufficient extent.

For *glass fibers*, the pretreatment is carried out by the glass fiber producer (sizing). These pretreated glass fibers can then be treated with an RFL-dip.

To promote adhesion of *polyesters* and *aramid*, a two-bath impregnating process was developed. A preliminary impregnating step is carried out before the RFL-dip, in which a blocked isocyanate is applied in combination with a polyepoxide.

Isocyanates. Polyfunctional isocyanates were used frequently in the rubber industry in the 1940s and 1950s. They have been widely replaced by RFL-dip. The reason for this is the restriction of handling organic solvents (in which the polyfunctional isocyanates are dissolved) and the much lower storage stability of the isocyanate dip prior to treatment with the rubber compound compared to RFL and treated textiles.

Isocyanate impregnating baths are still used occasionally, principally for particular adhesion requirements, since isocyanate-impregnated textiles show very high adhesion to rubber.

The RFS System [180, 181]. As an alternative or supplement to the impregnation of textiles, so- called direct adhesive systems are used. The chemicals required for promoting adhesion are added to the rubber compound during mixing.

The RFS system consists of the components **r**esorcinol, **f**ormaldehyde donors such as hexamethylenetetramine or hexamethylolmelamine (producers of hexamethylenetetramine are, for example, Degussa, Harwick, Housmex, MLPC; producers of hexamethylolmelamine are, for example, ACC, Bayer, Ceca, Koppers, Monsanto, Rousselot), and an active **s**ilica reinforcing filler. The resorcinol – formaldehyde resin, which promotes adhesion, is formed during vulcanization. The silica acts as a catalyst for the resin formation reaction and determines its rate.

In principle, various resin systems can be used. The state of the art involves using resorcinol together with hexamethylenetetramine or etherified hexamethylolmelamines. The importance of the former is rapidly decreasing because of the strongly corrosive action of the decomposition product (ammonia) on polyester and brass- coated steel cord.

Because of the strong tendency of resorcinol to sublime, substitutes for this compound are under investigation. Triazine derivatives or other polar phenols have been described as alternative resin-forming compounds in the patent literature but have not yet been widely used [182].

The RFS system can be used universally, both on textile carriers and on steel cords. It can be employed for the adhesion of rubber to untreated textiles and those impregnated with RFL. The best results are obtained by using RFS- containing rubber compounds with RFL-impregnated textiles.

Cobalt Adhesion Promoters. With the introduction of brass- coated steel cord into tire production by Michelin in the 1960s, organocobalt compounds began to be used as adhesion promoters. They function by stabilizing Cu_xS crystallites, which form a layer between the rubber and the brass. The latter is essential for good adhesion. Cobalt adhesion promoters are used mainly in the tire industry, but also in the conveyor belt sector. Examples are cobalt naphthenate, stearate, decanoate, and abietate.

Producers of cobalt adhesion promoters include Borchers, Manchem, Shepherd Chemical, and Vasset [183].

7.2. Rubber – Metal Bond [184 – 188]

The quality of articles made of rubber – metal composites is determined mainly by the quality of the bond between the two materials. Two processes can, in principle, be considered for the formation fo these articles.

The *adhesion* of vulcanized rubber parts to metal surfaces can be achieved by using polyurethane or polyisocyanate adhesives. This process is employed in linings and coatings. The disadvantages of the system lie in the low thermal, mechanical, and chemical resistance of the bonds.

The *bonding* of unvulcanized rubber compounds to metal surfaces can occur during molding and vulcanization. The bond between the elastomer and the metal is formed during vulcanization at 90 – 180 °C under the usual molding pressures.

The bond is produced by a binder system consisting of a primer and an adhesive. Factors relevant to quality are

1) Surface treatment of the substrate
2) Composition of the primer
3) Composition of the binder

If these three aspects are given proper consideration, the bond strength depends very little on the nature of the elastomer and the substrate to which it is to be bonded.

Surface treatment is naturally very important. The surface must first be cleaned and degreased by using aqueous or solvent- containing degreasing agents. It must then be extended and activated by mechanical or chemical processes (phosphating, see also → Metals, Surface Treatment, Chap. 3). Depending on the nature of the metal, a primer does not need to be used in the subsequent step with appropriate pretreatment. *Primers* are dispersions of chlororubbers in aromatics or ketones containing phenolic resins as the cross-linking agents and titanium dioxide or iron oxide as the pigment. Application to the cleaned and activated metal surface can be carried out by painting, spraying, dipping, or with rollers. The actual *binder* is then applied. Aromatics or ketones and, more recently, aqueous systems are used as solvent for the binder. The binders are complex systems composed of a polymer, resin, and reinforcing filler. Halogenated rubbers with high halogen content provide the best polymer base because of their high polarity. To achieve the necessary hardness, they are mixed with phenolic or epoxy resins. The reinforcement necessary to transfer strength properties is achieved by adding carbon blacks or silicas. Since halogenated polymers eliminate halogen in the form of hydrogen halide at vulcanization and processing temperatures, metal oxides, such as zinc or magnesium oxide, are added to absorb them. A complex cross-linking system must cross-link the polymer chains of the binder with those of the rubber compound and those of the primer, besides cross-linking the polymer chains in the binder. After the binder has dried,

it can be coated with the rubber compound and vulcanized in a mold under pressure.

A range of articles can be produced by using this process. These include shock absorbers, and articles used in sealing, transport, power transmission, and linings.

Producers of rubber – metal adhesive systems include Henkel, Lord Corp., and Chemetall.

8. Chemical Blowing Agents

8.1. Cellular Rubber Articles

Cellular rubber articles are produced using chemical blowing agents. These are almost exclusively organic compounds, which decompose at elevated temperature (see also → Foamed Plastics, Chap. 2.2). At least one of the decomposition products is a gas (e.g., nitrogen), which then produces foam structures in the rubber compound.

The decomposition of the blowing agents currently used is exothermic and irreversible, and takes place within a characteristic temperature range. The properties of an ideal chemical blowing agent were described in 1955 [189].

The decomposition temperature of the blowing agent in the rubber matrix is the most important factor determining the choice of agent. The incorporation of these agents into rubber compounds is carried out either in internal mixers or on open mixing rolls, with the decomposition temperature taken into account. For safety reasons the blowing agent is added separately from other additives as the last compounding ingredient.

Decomposition of the blowing agent occurs either during vulcanization (e.g., in the pressureless production of microcellular rubber profiles in UHF or LCM plants) or predominantly before cross-linking (e.g., in producing cellular rubber sheets by the expansion process).

The decomposition of the blowing agent and the cross-linking of the rubber compound must occur simultaneously for maximum utilization of the gas volume formed. This is particularly important in pressure-free vulcanization (e.g., profile production). If the coordination is not optimal (i.e., if vulcanization begins too early or too late), the blowing agent appears to be inadequate because of insufficient foaming. The decomposition of a blowing agent must not occur too spontaneously – in contrast to an explosive. Nitrogen is preferred as a propellant because of its low diffusion rate, which prevents cells from collapsing during foaming.

Chemical blowing agents are used for several reasons. Often a decrease in weight of the rubber article is desired. Since the latter is sold according to volume, a lowering in density is targeted. In addition, blowing agents are used to produce flexible materials for thermal insulation, which are of very low density. Shoe soles are produced from expanded rubber to increase the comfort of the wearer. The largest consumer of cellular rubber articles is the automotive industry. Here, microcellular rubber profiles are used for door and hood seals.

8.2. Product Types and Properties [190, 191]

Although in the past inorganic blowing agents (ammonium hydrogencarbonate, sodium hydrogencarbonate), which produced carbon dioxide as the propellant gas, were mainly employed, virtually only organic compounds are used today. These are more advantageous, despite their higher price, for the following reasons:

1) Significantly better dispersion in the rubber compounds
2) Higher gas yields
3) Production of gas over a narrower temperature range
4) Formation of nitrogen as the propellant gas, which has a much lower diffusion rate than carbon dioxide
5) Improved storage stability of rubber compounds containing blowing agents

The following organic compounds are sold as blowing agents for the rubber industry: *p*-toluenesulfonhydrazide (TSH), 4,4′-oxybis(benzenesulfonhydrazide) (OBSH), *N*,*N*′-dinitrosopentamethylenetetramine (DNPT), and azodicarbonamide (ADC).

Hydrazides. Hydrazine derivatives of organic sulfonic acids were developed by Bayer in 1949 as a new group of organic blowing agents

that produced nitrogen. Only two compounds from this group are still used for this purpose.

p-Toluenesulfonhydrazide is obtained by reaction of hydrazine with *p*-toluenesulfonyl chloride. The latter is formed in the chlorosulfonation of toluene for saccharin synthesis.

4,4′-Oxybis(benzenesulfonhydrazide) is produced by chlorosulfonation of diphenyl ether and subsequent treatment with hydrazine in an alkaline medium. Both sufonhydrazides are formed as relatively finely divided powders and are sold in this form or as preparations with paraffinic mineral oils.

***N,N′*-Dinitrosopentamethylenetetramine** is obtained by nitrosation of hexamethylenetetramine (urotropine). DNPT is a fine crystalline substance and is frequently produced as an 80 – 90 % mixture with an inert filler (chalk) and oil to desensitize it because of its very high decomposition rate.

Azodicarbonamide is produced from hydrazine and urea. The intermediate hydrazodicarbonamide is then oxidized to azodicarbonamide. Chlorine is used predominantly as the oxidant, but chlorates and hydrogen peroxide can also be used. Depending on particle size, azodicarbonamide is an orange to pale-yellow, crystalline powder (the smaller the particle size the lighter the color). Unlike the blowing agents TSH, OBSH, and DNPT, which are not ground for safety reasons (low decomposition temperature, or high sensitivity to abrasion or impact), ADC is usually ground up (e.g., in an air-swept mill). In this way, partially in combination with air classifying, ADC can be produced with a defined particle-size distribution. For the rubber industry, an average particle size of ca. 5 µm is common.

The blowing agents listed decompose at different temperatures. These temperatures are lowered, sometimes significantly, by the usual additives (zinc oxide, stearic acid, basic accelerators, etc.) present in a rubber compound. Table 10 gives an overview of these effects.

So- called *kickers* are used to lower the relatively high decomposition temperature and increase the rate of decomposition of azodicarbonamide [192]. These additives (zinc oxide, organozinc compounds, urea, and blowing agents such as TSH or DNPT) are added to the rubber compound as such or as a preparation with ADC (modified ADC).

Table 9 also gives an overview of the theoretical gas yields at standard temperature and pressure (STP).

For the sulfonhydrazides the data refer only to nitrogen. The water and steam produced in the decomposition of these blowing agents is not taken into account, because their effect on the blowing capacity can vary widely depending on the vulcanization process.

Reaction Mechanism. The decomposition of *sulfonhydrazides* can be formulated as follows

$$4\,R{-}SO_2{-}NH{-}NH_2 \rightarrow 4\,N_2 + 6\,H_2O + R{-}S{-}S{-}R + R{-}S{-}SO_2{-}R$$

sulfenic acid is first formed from the hydrazide, which disproportionates to form a disulfide and a polymeric thiosulfonate. Nitrogen and water are liberated in the process.

In the decomposition of *DNPT*, nitrogen is formed as the propellant gas. Small quantities of carbon dioxide, oxygen, water, formaldehyde, and nitric oxide have also been found. Traces of amines can be detected from their odor. This is generally regarded as the disadvantage of DNPT, since the fishy odor is transferred to the articles. In addition, a solid white residue is formed that has not yet been identified.

The decomposition of *ADC* is very complex. In the thermal decomposition of the dry substance in air the following quantities of decomposition products are obtained [191 – 193]:

gaseous products	32 %
solid residues	41 %
sublimate	27 %.

The gaseous products consist of

nitrogen	65 vol %
carbon monoxide	32 vol %
carbon dioxide	3 vol %.

The solid residues and the sublimate are composed mainly of urazole (39 %), cyanuric acid (26 %), hydrazodicarbonamide (2 %), and cyamelide (1 %). The figures are based on the quantity of ADC used.

The course of azodicarbonamide decomposition appears to follow two reaction pathways,

Table 10. Properties of organic blowing agents

Blowing agent	Decomposition temperature, °C	Gas yield at STP, mL/g	Heat produced on decomposition *, J/g	Start of decomposition in rubber compounds, °C	Lowering of decomposition temperature by
TSH	ca. 105	120	1531	ca. 85 – 90	basic substances
OBSH	ca. 165	125	1127	ca. 120	basic substances
DNPT	ca. 210	240	4352	ca. 120 – 130	acids, glycols, urea
ADC	ca. 200	220	1842	ca. 150 – 160	zinc oxide, bases, glycols, urea, acids

* Determined in nitrogen at 50 bar.

depending on the compounding formulation and the temperature:

$$H_2N{-}CO{-}N = N{-}CO{-}NH_2 \rightarrow N_2 + CO + H_2N{-}CO{-}NH_2$$

$$H_2N{-}CO{-}NH_2 \rightarrow NH_3 + HNCO$$

$$2\,H_2N{-}CO{-}N{=}N{-}CO{-}NH_2 \rightarrow H_2N{-}CO{-}HN{-}NH{-}CO{-}NH_2 + N_2 + 2\,HNCO$$

The hydrazodicarbonamide formed is the starting material for urazole (**54**).

54

Cyanuric acid is formed by trimerization of the intermediate cyanic acid. Both acids are also present in their tautomeric forms, isocyanic and isocyanuric acids. An additional solid polymerization product, cyamelide, is also formed.

The decomposition of the blowing agents is exothermic. Sometimes considerable quantities of heat are produced (Table 9) [194].

Since blowing agents do not decompose spontaneously because of their relatively high dilution in rubber compounds, generally no heat buildup occurs to yield undesirable consequences (e.g., local overcure or "burns" in the interior of the article).

The dosage of blowing agent depends on the desired density of the finished article, the proportion of filler, and the gas yield of the particular agent. The usual dosages are 3 – 10 wt % based on the rubber. In a few cases [e.g., for insulating materials with very low densities (<0.1 g/cm^3)] the dosage can be 30 wt % or more.

Economic Aspects. Individual blowing agents differ considerably in their industrial importance. *Azodicarbonamide* has the greatest market share. Azodicarbonamide and its modified forms are used to produce a wide range of porous rubber articles. The reasons for this are its relatively low price and high gas yield.

Sulfonhydrazides have decreased in importance because of their high price and low gas yields compared to ADC and DNPT. Also, the low decomposition temperature of TSH gives rise to problems in incorporation.

The importance of blowing agents based on *N,N′-dinitrosopentamethylenetetramine* has also decreased despite its high gas yields and low price. The reasons for this are the amine odor, the formation of compounds regarded as toxicologically harmful (formaldehyde, *N*-nitrosamines), and safety considerations concerning the handling of DNPT. The production and use of this blowing agent have been almost completely abandoned in Western Europe. DNPT is used predominantly in Asia for the production of expanded sole plates.

Storage and Transportation. Blowing agents can decompose violently under the effect of heat or on contact with certain chemicals (e.g., bases, acids, or oxidizing agents). On storage, transport, or handling of chemical blowing agents, warming should definitely be avoided. Storage temperature should be kept much less than 50 °C. These agents should therefore not be transported or stored near heaters, and other heat sources such as sunlight should be excluded. The proximity of sparks of flames (e.g., as a result of electrostatic charge buildup or welding work) should also be avoided.

If blowing agents decompose as a result of unforeseen external factors, intensive water cooling must be provided immediately. Only through this measure can the exothermic decomposition reaction be terminated.

Chemical blowing agents must not be transported by air for safety reasons. The various regulations and hazard classes must be adhered to for rail, road, or ship transport.

Producers and Trade Names. Important producers of blowing agents are listed in Table 11, together with trade names.

Table 11. Producers and trade names of chemical blowing agents

Producer	Trade name	Products
Bayer, Germany	Porofor	ADC, TSH
Dong Jin Chemical Ind., Korea	Unicell	ADC, TSH, OBSH, DNPT
Eiwa Chemical Ind., Japan	Cellular	ADC
	Neocellborn	OBSH
	Unifor	TSH
	Vinyfor	ADC
Herbron, Spain	Vinstab	ADC
Kum Yang, Korea	Cellcom	ADC, TSH, OBSH, DNPT
Olin Chemicals, United States	Kempore	ADC
Otsuka Chemical, Japan	Unifoam	ADC
Sankyo Kasei, Japan	Cellmic	ADC, TSH, OBSH, DNPT
Schering Industrial Chemicals, United Kingdom	Genitron	ADC, OBSH
Société Française d'Organo-Synthèse, France		ADC, OBSH
Uniroyal Chemical, United States	Celogen	ADC

9. Latex Chemicals [195], [196, pp. 621 – 652]

Latex is an aqueous, colloidal system. Therefore, water-insoluble substances in powder form must be incorporated into the latex in the form of dispersions because of their poor wettability, and liquid, water-insoluble substances in the form of emulsions. In addition to the usual chemicals in rubber such as sulfur, vulcanization accelerators, or antidegradants, the actual latex chemicals – e.g., dispersion agents, emulsifiers, stabilizers, thickeners, wetting and foaming agents, foam-stabilizers, antifoams, coagulating agents, and preservatives – play an important role in processing.

Dispersion Agents [195]. Sodium methylenebisnaphthalenesulfonate (condensation product of sodium naphthalenesulfonate and formaldehyde), which is used as a 2.5 – 10 % aqueous solution, has proved to be an effective dispersion agent, as has a 1.0 – 2.5 % ammoniacal solution of casein.

Emulsifiers [195, 197]. *Anionic* emulsifiers, such as alkali salts of fatty acids, can be applied in anionic latices. They are particularly important as wetting and foaming agents in latex technology. *Cationic* emulsifiers are of less importance because few cationic latices are used.

The most important emulsifiers in latex technology are the *nonionogenic* ones, such as poly(glycol ethers). They do not affect the charge on the latex particles. While poly(glycol ethers) show good stabilizing action toward the chemical effects of certain compounding ingredients, some poly(ether thioethers) do not. An increase in chemical stability may be undesirable if processing of the latex compound also includes a coagulation step.

Stabilizers [195] should impart stability toward mechanical and chemical effects as well as temperature changes, to the latex compound (for stability toward oxidative degradation, see Chap. 3).

Most emulsifiers (see above) are also stabilizers. Cationic emulsifiers generally give cationic latices particularly high mechanical stability.

Casein in the form of a 5 – 10 % ammoniacal solution is frequently used as a weak stabilizer. A small increase in the mechanical stability of synthetic latices can be achieved by adding sodium methylenebisnaphthalenesulfonate.

Wetting and Foaming Agents [195]. Common latices generally do not wet other materials sufficiently, even when they contain emulsifiers. To reduce the surface tension of the latex so that it is suitable for impregnation, addition of a *wetting agent* – usually an anionic emulsifier – is necessary. Sodium isobutylnaphthalenesulfonate and alkali sulfonates are highly active wetting agents for processing latex compounds. For certain synthetic latices, the addition of a wetting agent is superfluous, depending on the emulsifier system used for their production.

Whereas sodium isobutylnaphthalenesulfonate hardly has any foam-forming effect, which is desirable for the impregnation of smooth materials and coatings, alkali sulfonates are excellent *foaming agents*. They have proved particularly effective in combination with the soaps usually employed (e.g., sodium oleate).

In other impregnation processes, *antifoams* are often added to prevent surface damage caused by foam bubbles. Long-chain alcohols have some effect, but it is often inadequate. Some silicone oils are particularly effective.

Foam Stabilizers (for Production of Foamed Rubber Articles) [195]. In the processing of latex foam – both in the production of molded articles and in the finishing of foam-rubber-coated woven tissue – the foam poured into the mold or painted on the woven tissue often collapses before gelation and coagulation because of an increase in pore size. Poly(ether thioethers) have proved to be effective foam stabilizers, which inhibit the collapse of the foamed-up latex compound and at the same time lower its viscosity, so that it can be poured readily, even into complicated molds; they also prolong the period up to the start of gelation or coagulation. Better processibility, particularly in painting processes, is achieved.

Thickeners [195]. A relatively high viscosity is desirable for latex compounds used to coat textiles; it is also sometimes necessary for compounds for dipping, to achieve a certain wall strength. This applies particularly to certain synthetic latices, which have a relatively low polymer concentration and therefore too low a viscosity for certain processing purposes. However, the viscosity cannot exceed a certain level; otherwise, the very fine air bubbles present in the compound no longer rise to the surface, which leads to defective films.

Thickeners include polysaccharides, albumens, casein, tragacanth gum, pectin, glue, gelatins, and agar-agar. They are applied as 5 – 20 % aqueous solutions. Poly(vinyl alcohol) and polyacrylates are important synthetic thickeners.

Similar to emulsifiers and stabilizers, thickeners increase the swelling in water of articles made from synthetic latices. Therefore, only that level of thickener should be added that is necessary to achieve the targeted increase in viscosity, and excess thickener should be avoided.

Certain thickeners are also creaming agents and bring about creaming of less concentrated latex compounds. This is another reason why no more than the quantity of thickener needed to achieve the desired viscosity is used. The danger of creaming is less pronounced in more concentrated latex compounds.

For the reasons given, sometimes conventional thickeners cannot be used, so the latex compound is sensitized to a certain extent by the addition of substances such as electrolytes, heat-sensitizing agents, or acids. Sensitization is associated mostly with an increase in viscosity.

In certain cases a mineral filler, bentonite, is used, which increases the viscosity of the latex compound even at low dosages. Under some circumstances, however, addition of bentonite can lead to an undesirable thixotropic effect.

The increase in viscosity that can be achieved depends not only on the concentration of the latex and the nature and concentration of the thickener, but also on the chemical composition and specific colloidal properties of the latex, and the molecular structure of the rubber material.

Coagulating Agents [195, 198]. One stage of latex processing is always coagulation. Almost all synthetic latices are considerably more resistant to the sensitizing effects of coagulating agents than natural latex, because of the relatively high content of emulsifiers used in polymerization.

Coagulating Agents with Powerful and Spontaneous Action. Electrolytes, e.g., carboxylic acids (formic acid, acetic acid, and lactic acid), polyvalent metal salts (calcium and aluminum chlorides or nitrates), and organic salts (cyclohexylamine acetate), are also used as coagulating agents. With natural latex, a compact coagulate is obtained; whereas latices of nitrile or styrene – butadiene rubber coagulate as flakes or crumbs.

Like natural latex, most chloroprene rubber latices form a compact coagulate with powerful and spontaneously acting coagulating agents. However, the coagulating agents must be employed with chloroprene rubber in a higher concentration than with natural latex.

Weak Coagulating Agents That Act Only Gradually or on Warming. Ammonium salts,

zinc oxide, sodium and potassium silicofluoride, 2-mercaptobenzimidazole and its zinc salt, zinc 2-mercaptobenzothiazole, poly(vinyl ethers), poly(oxypropylene glycol), and certain functional siloxanes are weak coagulating agents.

The action of weakly coagulating electrolytes is based on a gradual discharge of rubber particles, which leads to an increasing sensitization of the compound. The compound coagulates on warming or with continuing sensitization at room temperature. One theory of heat sensitization states that heat-sensitizing agents are generally compounds with a polyether chain. Such compounds absorb water at room temperature. At increased temperature the water is eliminated. In this state the molecules are capable of forming adducts not only with one another, but also with nonionic and anionic tensides. Through adduct formation the tensides are no longer in a position to exercise their actual function, which is to stabilize the latex compound; they are precipitated as insoluble adducts. This leads to sudden coagulation, whereby a closed seamless gel film is formed on the mold.

Although poly(vinyl methyl ether) and poly(oxypropylene glycol) are very suitable for heat sensitization of natural latex, their action on latices of nitrile and chloroprene rubber is unsatisfactory. The best agents for the latter are certain functional siloxanes.

Preservatives [195]. In many cases, casein or hemoglobin solutions, which tend to putrefy with time, can be formed in latex compounds, thus giving the latex an unpleasant odor. This putrefaction can be hindered by the addition of sodium *o*-phenylphenolate, for example.

Rubber Chemicals for Latices [195]. All rubber chemicals are added in emulsion or dispersion form if they are water insoluble or in aqueous solution if they are water soluble. The water used is soft (i.e., distilled, condensed, or rainwater).

A prerequisite for problem-free vulcanization of latex articles is uniform distribution of sulfur in as fine a form as possible, so that sedimentation in the latex compound is effectively avoided. The use of colloidal sulfur in latex compounds is therefore particularly recommended.

Only the most rapidly acting *vulcanization accelerators* (i.e., dithiocarbamates) are generally used. For *protection against aging*, nonstaining phenolic or weakly staining aminic antidegradants are used.

The addition of *fillers* to latex compounds does not give a reinforcing effect like that observed in solid rubber technology. Therefore, only inactive, white fillers are used, if at all. An exception is the action of certain silica sols in natural latex.

The addition of *plasticizers* is unnecessary. Sometimes paraffinic oil, plant oil, or ether plasticizers are added to achieve particularly low modulus articles (e.g., for toy ballons). Chlorinated paraffins are added to provide flame resistance.

10. Flameresistant Rubber Articles

10.1. Combustion Process in Polymeric Materials

Rubber articles, such as underground conveyor belts or cables, should maintain their function for as long as possible in the event of fire. For this reason, flameresistance is absolutely essential. In the event of fire, thermal decomposition precedes actual ignition of a polymeric material. This decomposition occurs as a result of the effect of energy sources and leads to gaseous decomposition products, which, combined with atmospheric oxygen, form an ignitable mixture. Since further decomposition with exothermic oxidation takes place in the region of the energy source, the temperature of the gas mixture and the concentration of combustible gas increase.

If a concentration threshold and a temperature specific to a particular substance are exceeded, the mixture of oxygen and heated decomposition products ignites. At this point, most of the organic bonds in the polymer molecule are broken down. Carbon black, carbon dioxide, and water are formed in the flame. The energy liberated in this reaction then decomposes more polymer material and increases the quantity of decomposition products.

A complex series of chain reactions involving free radicals has been discussed for this oxidative decomposition of hydrocarbon polymers [199 – 201].

10.2. Testing of Flammability

Testing of the flammability of rubber is carried out mainly on finished articles. In the case of conveyor belts and driving belts, underground behavior is particularly important. Tests are prescribed in appropriate national standards. Similar considerations apply to the cable sector. The oxygen index (LOI), described in ASTM D 2863, gives an initial indication of the fire resistance of rubber compounds. The test determines the concentration of oxygen at room temperature, at which a rubber test article in a glass tube is still extinguished within 3 min after being ignited from above.

10.3. Inhibition of Combustion

As has already been mentioned, the combustion process can be divided into two different stages:

1) Formation of a combustible gas mixture from a polymeric material (pyrolysis)
2) Combustion of the pyrolysis products by a radical mechanism

Effective flameproofing can thus act at either stage. Inhibition of pyrolysis involves suppressing or slowing down the formation of all combustible products. This is achieved by using *fillers*. High dosages of inorganic fillers dilute the combustible polymer per unit volume, so that if ignition occurs, the quantity of pyrolysis products is reduced. This measure has a certain effect if flame-resistant, inactive fillers such as chalk or kaolin are applied, but in most cases is inadequate.

A much better effect is achieved by using inorganic fillers, which also undergo an endothermic reaction as a result of energy supply by an ignition source. The most important example is aluminum hydroxide, $Al(OH)_3$. Energy converts aluminum hydroxide into the inert aluminum oxide. This reaction takes place with elimination of water and is strongly endothermic (1211 kJ/kg aluminum hydroxide). The steam produced dilutes the pyrolysis products in the gas phase, and the energy necessary for its formation is no longer available for pyrolysis of the polymer. If all the aluminum hydroxide is converted into Al_2O_3, the residual oxide acts as a fire retardant only by diluting the polymer. Magnesium hydroxide is also used as a fire retardant but is commercially much less important.

A third effect can be observed when using zinc or calcium borate. In the event of a fire the borate melts and forms a sintered surface so that the rubber layer below is protected for a time against the decomposing effect of the ignition source.

The combustion of pyrolysis products is a radical chain reaction. According to SCHMIDT [202], a determining factor for the combustion rate is the increase in quantity of highly reactive OH radicals. All compounds that can replace these highly reactive species by less reactive radicals lower the combustion rate. The most important groups are chlorine or bromine compounds, which react according to the following mechanism.

$$RX \rightarrow R\cdot + X\cdot$$

$$X\cdot + RH \rightarrow R\cdot + HX$$

$$\cdot OH + HX \rightarrow H_2O + X\cdot$$

where X = Cl, Br

How readily HCl or HBr is liberated is decisive for the degree of flameproofing. In practice, chlorinated or brominated paraffins are used. The use of polychlorinated or polybrominated aromatics is decreasing sharply because of the possible risk of dioxin formation. Antimony oxide has a synergistic effect on the fire-retardant action of halogen compounds. The exact course of the reaction is not yet completely understood. However, the formation of $SbCl_3$, which decomposes in cooler areas near the flame via a series of stripping reactions with the formation of HCl, is undisputed [203].

1. Latex Processing

Wolfram von Langenthal

Compared to the amount of solid rubber consumed, the quantity of latex that is processed as such is small. In 1992, worldwide natural rubber consumption was 5 125 000 t [of which 560 000 t (10.9 %) was processed directly as latex], and synthetic rubber consumption was 9 192 000 t [of which 1 710 000 t (18.7 %) was processed directly as latex]. These latex quantities are calculated in terms of solid matter so that all figures can be compared directly. The Brussels customs nomenclature differentiates between synthetic rubber latices and other polymer dispersions [i.e., poly(vinyl chloride), ethylene – vinyl acetate copolymer, or polyacrylates]. Irreversible conversion of the polymer from the thermoplastic to the elastomeric state by vulcanization is used as the criterion for identifying a synthetic latex. The conversion is determined by the stress – strain behavior of corresponding polymer films.

Only the smallest quantities of latex are processed by the rubber industry. A much greater demand comes from the textile, paper, and leather industries and the producers of paints and varnishes.

Synthetic latices are virtually always produced by emulsion polymerization. Unlike emulsion rubbers (⟶ Rubber, 3. Synthetic), reaction is carried out to a higher degree of polymerization, which leads to more branching, but also to more intense cross-linking of the polymer chains. The degree of branching and cross-linking is varied, depending on the latex type; for example, it can be held back, as in foam latices, or even deliberately increased, as in reinforcing latices.

Synthetic latices consequently have a higher solid material content than latices that are used for the production of emulsion rubbers. This is desirable, partly for industrial processing but mainly for transportation and storage.

For latices, in addition to the characteristics of the polymer itself, the colloidal properties of the latex are of considerable importance for their application. They affect the processability of the latex and the film-forming characteristics of the polymer.

Synthetic latices can be classified into three categories: those without reactive groups, those with groups capable of reaction, and polymers with groups capable of self- cross-linking. Those without reactive groups are cross-linked by vulcanization provided they are diene polymers. Polymers containing reactive groups, mainly carboxyl, can be cross-linked by the addition of a second component such as a heavy-metal oxide or precondensed amino resins. Reactive polymers contain groups that react at elevated temperature with one another or with other reactive groups introduced by copolymerization, resulting in cross-linking. Examples of these are *N*-methylol groups and their esters or ethers.

The mechanical properties of *vulcanized latex films* are similar to those of corresponding rubber sheets. Their sensitivity to water, i.e., swelling, is however, greater than that of corresponding rubber sheets because of the higher emulsifier content of latex films.

Freshly tapped *natural latex* contains, besides 32 – 40 % rubber, 2 – 3 % proteins and lipoids, 0 – 3 % resin, 1.5 – 4 % glucosides, and 0.2 – 1.0 % inorganic substances. On concentration by centrifugation a large proportion of these other latex components is removed with the serum [1].

The remaining latex components represent the colloidal chemical system, which maintains the metastable latex state. All *synthetic latices* differ from natural latex in this respect, since the former all contain tensides as stabilizers. In some instances, emulsion polymers are free from surfactants. In such cases, however, the polymer contains hydrophilic, preferably sulfate, groups. Because of their soap content the compounding of synthetic rubber latices is different from that of natural rubber (NR) latex. This often results in very different processing techniques. NR latex may be prevulcanized by adding sulfur and ultraaccelerators (⟶ Rubber, 4. Chemicals and Additives); and heating it for a prolonged period of time at 70 – 80 °C under continuous slow agitation. Prevulcanized NR latex is referred to as Revultex. Excess vulcanization agents are removed with the liberated serum in subsequent centrifugation. By drying at low temperature, films, which already show a certain vulcanization effect, can be produced from this Revultex. Similarly pre- cross-linked SR latices can be produced but are not available on the market [2], [3].

Latex polymers are characterized by the same international abbreviations as solid rubber grades. The letter X in front of the abbreviation indicates that the polymer contains reactive groups. Compounding ingredients are always calculated on the basis of 100 parts latex dry substance (phr).

1.1. Latex Testing [4]

Production monitoring by the producer and raw material control by the processor are equally important for maintaining the quality of latices and of the finished products made from them. ISO and respective national standard methods provide a framework for quality assurance. The latices are homogenized before sampling for quality control. Important *latex parameters* are as follows:

The content of coagulum is determined by filtration through variable filtration media, depending on the requirements. Gravimetric evaluation of coagulum content is possible, but visual assessment is usually sufficient [5].

The total solids content is determined by gravimetric analysis of a latex sample dried to constant weight [6].

The dry rubber content is determined by precipitation of the latex with suitable watermiscible solvents, such as acetone or isopropanol, sometimes with the aid of electrolyte solutions. After complete precipitation, the flocculated polymer is carefully freed from the other latex components by washing, and dried to constant weight [7].

The pH value is measured by using glass electrodes [8].

The surface tension is determined with the ring-detachment method.

The density of the latex is determined with a pycnometer [9].

The particle-size distribution can be obtained by various methods, all of which have their advantages and disadvantages. Examples are electron microscopy, ultracentrifugation, and light diffraction measurements. Generally, determination of the average particle size is sufficient (e.g., by turbidity photometry, static light scattering, or laser correlation spectroscopy). The reliability of the method of measurement also depends on the particle-size range, which should be scanned.

The viscosity is measured with a rotation viscometer. In practice, determination of the relative viscosity, which is obtained by measurement of the flow rate from a standard beaker with a defined orifice outlet, is usually sufficient [10].

The mechanical stability of the latex is affected by many factors. Only the measurement of the shear stability by using a high-speed disc stirrer (Klaxon instrument) has been standardized. The stirring time at 14 000 rpm until the first coagulated particles are formed is used as a measure of the mechanical stability [11]. In processing, other factors such as the drying rate also affect the stability of latex compounds. Thus, for control of the mechanical stability in the laboratory, special methods (e.g., squeeze-roller stability, stirrer test) must be worked out.

The chemical stability is a measure of the compatibility of the latex with various additives, such as vulcanization agents, resins, and fillers. Here also, specialized methods are often indispensable. The zinc oxide stability test, which involves addition of a finely dispersed zinc oxide to the latex, subsequent warming, and measurement of the temperature at which coagulation begins, is widely used. It cannot be applied with latices of polymers containing carboxyl groups. The chemical stability of latices is also frequently measured by titration with $CaCl_2$ solution.

The setting point is the temperature at which the latex thickens significantly just before freezing. It is a measure of the minimum storage temperature.

The coagulation point of heat-sensitizable latices is defined as the temperature at which a standard test compound coagualtes quantitatively under defined heating conditions and during slow stirring.

The gelation time is determined at 20 °C for foam compounds, to which a defined quantity of gelling agent (e.g., sodium silicofluoride or ammonium acetate solution) has been added.

The residual monomer content is usually determined by gas chromatography and is specified by latex producers as the upper limit in the safety data sheet or, on special agreement, as a specific value in the test report accompanying the product supplied.

Bacterial contamination is defined by determining the bacterial count.

The following tests are used for characterization of the *polymer* itself.

The white point temperature and the minimum film-formation temperature, as indirect measures of polymer hardness, are determined by drying the latex on a metal block with a defined linear temperature gradient along its length.

The Mooney viscosity and deformation hardness are measured for precipitated polymers in the same way as for solid rubber. Neither determination can be used for polymers with self- cross-linking groups, because the plasticity of the polymer might have been altered uncontrollably by pre- cross-linking and can change further during measurement [12].

For further characterization of the polymer, *films* are cast from the latex and dried.

The film hardness, measured with a Shore instrument, gives information on the polymer hardness. It is also applicable to reactive polymers [13].

The glass transition temperature, as an indirect measure of polymer hardness, is determined on films.

Tensile strength, tensile elongation, and elastic modulus are normally not provided by the latex producers. They are parameters used by the processor to test suitability and can also be used as relative values for determining the cross-linking or cross-linkability of the polymer. The measurements are carried out on films [14], [15].

1.2. Transportation, Storage, and In-House Distribution of Latices

The cost of transportation and storage of latices is very high, as with all liquids. Small quantities are transported in drums or containers, large ones in tankers. Apart from some exceptions, latices are sensitive to frost, which should be taken into account during transportation and storage. To stock up for the winter is therefore not unusual.

In addition to frost protection, containers must be kept closed so that no skin formation occurs as a result of evaporation of water. Storage tanks should be equipped with stirrers so that the latex can be homogenized after long storage periods. Phase separation can be prevented from the beginning by continuous slow stirring.

In the in-house distribution of latices and their compounds, their limited shear stability must be taken into account. Therefore, only feed pumps imposing low shearing force on the substance fed may be used. Feed pipes and pumps must always be kept filled with latex or latex compounds, so that polymer film formation by drying of latex residues is avoided. They should be readily accessible and exchangeable, so that cleaning work can be carried out without halting production.

1.3. Compounding and Compounding Formulation

1.3.1. *Additives*

Additives can be classified as those with colloidal effects, rubber chemicals in the actual sense, or fillers and pigments.

1.3.1.1. *Colloidally Active Substances*

Emulsifiers are added to latices to increase their mechanical and chemical stability. Anionic, cationic, or nonionic surfactants are chosen, depending on processing requirements. Nonionic surfactants show the best emulsifying and stabilizing effect at low temperature, their solubility decreases with increasing temperature. They are therefore preferred as stabilizers in heat-sensitive compounds. Anionic emulsifiers promote foam formation and are particularly suitable for latex compounds that are to be frothed. Cationic emulsifiers are very rarely used, and only in cationic latices, if these might be stabilized to an undesirably large extent by nonionic or amphoteric surfactants.

Protective colloids, such as caseinates, or certain thickeners and complexants, such as sodium hexametaphosphate, are specified as *stabilizers*. These also stabilize the latices against mechanical, chemical, and thermal effects.

Wetting agents can be important in impregnating processes to guarantee perfect penetration of the substrate by the latex compound.

Foaming agents are generally anionic surfactants, such as fatty acid soaps, fatty alcohol sulfates, and alkyl, aryl, or aralkyl sulfonates, succinates, and amidosulfosuccinates (succinamates). Surfactant combinations of uniform ionogenity always froth more intensely than mixtures of anionic and nonionic ones. Thickeners are important as foam stabilizers, in addition to functioning as protective colloids (see above).

Antifoams are used to avoid or destroy foams in various processing procedures. Silicone antifoams are generally more active than others but can easily produce “fish eyes” in smooth latex films (e.g., dipped goods). Their abhesive effect is prohibitive for the use in cord dipping compounds.

Coagulating agents with spontaneous action are used for dipped articles (predipping solution), in precipitation baths for spinning rubber threads, and in latex employed in pulp processes. Acids and salts of polyvalent metals, such as alkaline earths and aluminum, are normally used. Coagulating agents with delayed action, such as sodium silicofluoride or ammonium acetate, are used as gelling agents for foam production.

Heat-sensitizing agents are polyethers that are added to the latex compound and bring about spontaneous quantitative coagulation of the system at an elevated temperature that depends on the compounding formulation. At room temperature these compounds remain stable for long periods. Suitable products are poly(vinyl methyl ether), poly(oxypropylene glycol), poly(siloxane ether), quaternary poly(ether amines), and certain water-soluble polyetherpolyurethanes [16-20].

1.3.1.2. *Rubber Chemicals*

Rubber chemicals that are used in latex must be distributed as finely as possible in aqueous systems. Fine-grained zinc oxides of basic zinc carbonate, and flowers of sulfur or colloidal sulfur, are preferred to other types of zinc and sulfur chemicals.

Only the most active *ultra accelerators* can be used with latices. For NR, nitrile rubber (NBR), and styrene – butadiene rubber (SBR) latices, these are the dithiocarbamate and mercapto accelerators. For polychloroprene (CR) latices, thiourea and guanidine accelerators are used. As with solid rubber, accelerator combinations are almost always applied. The accelerators named are water insoluble. For some processes, water-soluble accelerators are employed (e.g., sodium diethyldithiocarbamate and pentamethyleneammonium-*N*-pentamethylenedithiocarbamate and xanthate).

Polymers containing carboxyl groups can be cross-linked ionomerically with zinc oxide but also with precondensed amino resins by condensation. Self- cross-linking polymers contain thermoreactive groups, such as *N*-methylols. They react with one another and with carboxyl or amide groups by condensation reactions.

With the exception of the paper industry, *antioxidants* are usually added by the producer to latices of polymers having reactive groups. Further addition of antioxidants is then necessary only if very particular stability is required. In the case of all other latices the antioxidant must be added by the processor. Sterically hindered mono-, di-, and polynuclear phenols, benzimidazoles, dihydroquinolines, and arylamines are important antioxidants in latex processing. Synergistic effects are known in latex processing, as with solid rubber. There are no water-soluble antioxidants. Ozone protection is rarely required for latex articles. The effect of ozone protection agents is increased by ozone protection wax.

Water-insoluble, powder rubber chemicals must be dispersed before addition to the latex, and oily substances must be emulsified. Water-insoluble chemicals have the advantage that they remain almost quantitatively in the polymer during processing and are not removed in uncontrollable quantities with the serum, as water-soluble ones are.

1.3.1.3. *Fillers and Pigments*

In contrast to solid rubber, there are no active fillers for latices. Whiting, china clay, slate flour, barytes, and other materials undoubtedly have reinforcing action, but are used primarily to make the product cheaper or to increase its weight. In the case of paper coatings and latex paints the pigment is the most important component; it imparts the effect and the latex acts as a fixative. Aluminum oxide hydrate improves the flame retardancy of articles. Fillers can generally be stirred directly into the latex without predispersion. Colloidal silica is added in some cases to achieve a dry surface of the polymer. It can be added to the latex only as an aqueous preparation.

Inorganic and organic pigments are added for coloration. They must be resistant to vulcanization conditions and free from rubber toxins. Among the carbon blacks used as black pigments, those that are preferentially absorbed by the polymer, and will not be washed out with the aqueous phase, should be selected. In the case of organic pigments, those that have no migration tendency should be employed to ensure constancy of color.

1.3.2. *Compounding*

All *powder additives,* with the exception of most fillers, must first be dispersed in water by using a suitable dispersion agent. Ball, pearl, or for small quantities, laboratory mills with centrifugal action are used for this purpose. The particle size of normal dispersions of rubber chemicals is between 0.1 and 50 µm, and preferably 1 – 5 µm. Perfect distribution of such particles in the latex compound is guaranteed. All solid materials to be added to a latex compound can be dispersed together.

Oily and *waxy compounding ingredients* are emulsified before they are added to the latex. For this purpose, high-speed stirrers are used, which develop strong shear forces. The choice of emulsifier depends on the substance to be emulsified. Two or more emulsifiers are often used to achieve optimum results. Water-in-oil emulsions are rarely used in latex processing, because they generally increase the viscosity of latex compounds.

In production, the order of addition of various components to the latex is often of critical importance for the stability of the compound. No fixed rules exist. Preliminary tests should be carried out in cases of doubt. In any case the latex is stabilized first if necessary. Viscosity and pH are adjusted at the end.

1.4. Processing Procedure

Latex processing is divided into three sections in what follows: Processing of true rubber goods, processing to give compounds, and application to substrates.

1.4.1. *Processing of Rubber Articles*

1.4.1.1. *Dipped Goods [21]*

Dipped articles are seamless hollow articles that are formed from polymer solutions or dispersions by complete coating of a mold surface, followed by drying and cross-linking of the coating. The molds are coated by dipping them briefly into the polymer solution or dispersion so that polymer precipitates on their surface.

In some cases the opposite principle is used. A hollow mold made of separable parts that can be opened is filled with the latex mix, and after forming a layer by precipitation on the inner surface of the mold, the excess is poured out.

The latex compounds precipitated on molds are dried in hot air and vulcanized. Immediately after dipping, the mold is rotated continuously to achieve uniform thickness of the latex layer and prevent drip formation. The mold can be reused more quickly if the article is removed after drying and vulcanized in a tumbler.

Articles with *very thin walls* (e.g., condoms) are produced by dipping the mold briefly into the vulcanizable NR latex compound, drying, further dipping to avoid defects, renewed drying, and vulcanization.

Coagulant or Predipping Process. If thicker walls are required (e.g., for gloves) the coagulant process is used. The heated molds are first dipped into an aqueous, alcoholic, acetonic, or mixed solution, usually of calcium nitrate. The mold is then turned several times so that the solution is distributed uniformly over the mold's surface and is further concentrated by evaporation. The mold thus coated, is then dipped into the latex compound, which is coagulated by the electrolytes and deposited on the mold surface as a gel.

The concentration of the electrolyte solution and the residence time of the mold in the latex compound affect the thickness of the layer of gel formed. With increasing thickness the diffusion rate of the electrolyte solution decreases. The wall thicknesses that can be achieved are therefore limited to ca. 0.8 mm. Before vulcanization the coated mold should be rinsed to remove water-soluble components.

The coagulant process allows two-layer construction of hollow articles. After gel formation on the mold, the latter is dipped into a second latex compound and an additional gel layer is formed by the electrolyte solution diffusing through the first layer. CR – NR laminates are produced in this way. The adhesion to one another is excellent.

Heat Sensitive Process. Very high wall thicknesses (e.g., in nipples for baby bottles and electrician gloves) can be achieved by the heat sensitive process. By addition of heat-sensitizing agents to the latex compound [poly(vinyl methyl ether) to NR latex and organopolysiloxanes to SR latex], compounds are produced that are stable over long periods if stored at ca. 20 °C, but coagulate spontaneously at elevated temperature, generally 36 – 40 °C. Molds that have been warmed to ca. 70 – 90 °C are dipped in the latex compound, which is then spontaneously precipitated on the surface as a gel with relatively high thickness. The temperature and heat capacity of the mold and, to a small extent, the residence time in the latex compound affect the thickness that can be achieved. The limit here is ca. 4.0 mm.

Textile-reinforced gloves can be produced by the coagulation and the heat sensitive processes. A tightly fitting knitted glove is pulled over the mold and the process is carried out as described. For these types of protective gloves, the rubber layer must adhere perfectly to the textile, but the latex compound should not penetrate it. The latex compounds are thickened to inhibit this penetration.

1.4.1.2. *Rubber-Coated Metal*

Corrosion-resistant coatings are produced on metal surfaces by electrophoretic precipitation of latex compounds. Such surface rubberization must often be hard and scratch resistant. For this, ebonite compounds produced from NR latex, which are vulcanized with ca. 45 phr sulfur, are used [22].

1.4.1.3. *Rubber Threads*

A vulcanizable NR latex compound containing zinc 2-mercaptobenzothiazole (ZMBT) as accelerator and secondary sensibilizer is extruded through glass spinnerets into a precipitation bath containing acetic acid. The acetic acid flows in the direction opposite that of extrusion. After complete coagulation the threads are washed to remove acetic acid, which impedes vulcanization, and other water-soluble substances from the gel. The gel is then dried and vulcanized. The latex threads may come into contact with one another only after predrying; before that, they would adhere to one another irreversibly. The rubber threads are produced in diameters of 0.2 – 1.2 mm [23].

1.4.1.4. *Cast Articles*

Articles produced in hollow molds by casting can be considered a special category of dipped articles. Metal molds, which are used with heat-sensitive latex compounds, are comparatively rare. They are employed in the production of meteorological balloons, for example. Porous hollow molds of porcelain or gypsum are most frequently used. Here, the precipitation of the polymer takes place mainly by absorption of the serum through the pores. Very high wall thicknesses are achieved in this way. Hollow articles with small openings, such as hot-water bottles and toy animals, can be produced by this method. The latter are the only latex articles of this type that contain a great proportion of filler — up to 300 phr whiting or china clay. The porous molds gradually become clogged with serum components and thus rendered unusable [24].

1.4.1.5. *Molded Foams [25]*

The well-known molded foams for mattresses, upholstery, shoe parts, etc., are produced from NR or SBR latices. Sulfur, zinc oxide, and accelerator combinations are added for vulcanization, in addition to antioxidants. To achieve foamability, a surfactant is added to the latex (e.g., an aqueous solution of potassium oleate). Surfactant mixtures and, in certain cases, small quantities of thickeners can be used to improve foam formation, stability, and structure (see Section Colloidally Active Substances). A particular characteristic of the foam structure is produced by the addition of diphenylguanidine or triethyltrimethylenetriamine to the vulcanization system. These accelerators contribute less to the vulcanization but more to improving the foam structure and making it more uniform. For perfect foam formation and as small a decrease in volume on drying as possible, compound systems are used that have the highest possible concentration.

In foam production the mechanically produced latex foam is first gelled and then vulcanized. Either the Dunlop or the Talalay process is used.

Dunlop Process. By far the greatest proportion of molded foams is produced by the Dunlop process. Here an aqueous sodium silicofluoride dispersion is added to the readily mixed, vulcanizable latex compound during the mechanical foaming process. The quantity depends on the desired potlife of the foam compound, which is generally adjusted to 8 – 12 min, which is sufficient to fill the foam molds. Contrary to NR latex mixes, SBR latex mixes need not be completely gelled at room temperature before the closed molds are heated in saturated steam (100 °C) to vulcanize the latex foam. After vulcanization the articles are removed from the mold, washed, and dried. Small foam articles for the shoe industry are

produced in open molds. As soon as these are filled and the excess foam has been removed with a doctor blade, they are gelled in an IR field, dried in hot air, and vulcanized. No subsequent washing is necessary.

Talalay Process. In the Talalay process the vulcanizable latex compound is frothed in a mechanical mixer, to give a foam with relatively high density, and then poured into molds. The closed molds are evacuated. The latex compound foams to its final density because of the vacuum applied and thus fills the mold completely. By cooling the mold to ca. – 30 °C the structure of the foam is fixed. Carbon dioxide is led into the mold, thus lowering the pH of the frozen foamed latex compound, which then gels. The foam may now be thawed without changing its structure, and the mold is heated in stages to 110 °C. After vulcanization is complete, the article is removed from the mold, washed, and dried.

Foams from CR latex generally have lower compression resistance than those from NR or SBR latex. The compression deflection properties can be improved by addition of aromatic or aliphatic diisocyanates, e.g., methylenediphenyl-4,4′-diisocyanate (MDI), during foaming. However, in this case the pH of the strongly alkaline latex compound, which can be as high as 12, should be adjusted to 10. Salts of a strong acid and an amine (e.g., diethanolamine hydrochloride) are used for pH adjustment.

The vulcanization agents and antioxidants usually used in processing CR latex are added here also [26].

1.4.2. *Processing of Functional Materials*

1.4.2.1. *Can Sealants*

Filled food cans cannot be sealed by soldering. The joint grooves of the lid are filled with an elastic lining to achieve absolutely tight joints. These aqueous sealing materials must correspond to appropriate food regulations. They consist of polyester resin with a melting point of >100 °C, resinates, filler, high-solid SBR latex, antioxidants, pigments, leveling agents, and thickeners. Very specific rheological requirements are imposed on the finished sealants, because they must be sprayed onto the lid without dripping or be stamped on avoiding stringiness [27], [28].

Because of the high chemical resistance of the polymer, CR latex is used for sealants for *varnish and spray cans*. The compounds also contain components that are resistant to various chemicals and not necessarily the above-mentioned resins.

1.4.2.2. *Adhesives*

Water-based adhesives are continually gaining importance because of safety standards at the workplaces and environmental protection. *Poly(vinyl acetate) dispersions* are probably the oldest and most widely used adhesives of this class. They are mainly used for wood and packaging. *Polyacrylate dispersions* have a substantial market in the building industry (e.g., for tiles and floor coverings). *Polyurethane dispersions* are replacing solvent systems in the automobile and shoe industries. They are also important for the adhesion of formica sheets to chipboard and fiberboard, particularly for kitchen furniture. *SBR latices* are used as packaging, expanded polystyrene, and in the building industry. *CR latices* are playing an increasingly important role as shoe adhesives, but are also used for adhesion of upholstery foam.

In processing to manufacture adhesives, polymer dispersions must often be mixed with thickeners, emulsifiers, and protective colloids for stabilization; resins to increase tackiness; possibly leveling agents; fillers; etc. Cross-linking by using resins or isocyanates that react sluggishly with water is often employed, whereas classical vulcanization is not [29].

1.4.2.3. *Elastified Concrete*

The addition of NR, CR, or SBR latices to cement – sand mixtures gives good adhesion of the concrete to various surfaces (e.g., metal or old concrete). In addition, the concrete is elastified, which renders the layers less prone to cracking. The latex used must be sufficiently stable during compounding to avoid coagulation by the electrolytes present in the cement. In addition, it must not impair the hydraulic binding of the cement. The polymer is not cross-linked. Elastified concrete is used, for example, in ventilation engineering in mines; for coating metal air channels to suppress flow noises and vibration; as a covering for decks of ships; and for vibration-proof floorings. Since it usually hardens rapidly, it is mixed in small quantities and applied by troweling [30].

1.4.2.4. *Modified Mortar and Fillers*

The elastic properties and good adhesion, that are achieved with elastic concrete are used for special mortars and fillers. For the latter, horizontal and lateral adhesion plays an important role, as does the priming effect for the adhesion of the subsequent surface layer (e.g., in PVC floor coverings or carpeting) [30].

1.4.2.5. *Paints*

Latex is important as a binder for latex paints for indoor and outdoor use. Polyacrylate and vinyl acetate copolymer dispersions are the most widely used raw materials. XSBR latex is less important because of its slight tendency of discoloration. Large quantities of filler are incorporated into the latex without any problem, as demonstrated particularly well by structured interior and decorative plasters. Pigment distribution and binding do not pose any problems either. The rheological properties of latex paints are important for surface structure and layer thickness. Therefore, thickeners of varying rheological characteristics are incorporated into the compounds, depending on the desired effect [31].

1.4.2.6. *Bitumen Modifications*

Both hot bitumens and bitumen emulsions are modified with latices. The thermoplastic bitumen is elastified by the incorporation of elastic segments. Optimal effects over long periods are obtained if the rubber particles swell in the bitumen, which achieves efficient blending.

Anionic bitumen emulsions can be mixed readily with latices. Besides elastification, the addition of latex improves the low-temperature flexibility and raises the softening point of the bitumen. The addition of 10 – 20 % latex based on solids

content, is usual. Bitumen emulsions modified in this way are used as moisture barrier in underground structures and in roofing. The bituminous sealing layers can be exposed to building movements without cracking. The lowering of the brittle-point and raising of the softening point contribute to the weather resistance of roofings.

Cationic bitumen emulsions are modified with cationic latices, so that their breaking characteristics are not affected. Modified cationic emulsions are used for surface treatment in road construction. The modified emulsion breaks immediately after application. The bitumen – latex mixture therefore does not flow away from the road even during light rain and remains completely available to bond chips. Modification with latex improves adhesion of the gravel and the weather resistance.

Hot bitumen is modified by spraying the latex on the hot stirred mixture, which is generally at a temperature of more than 180 °C. The water in the latex evaporates immediately on the surface, and only the rubber particles are blended mechanically into the hot bitumen. Modification with latex has the advantage, compared to the use of polymer powders, of much finer distribution because of the considerably smaller size of the latex particles. The quantities of latex used are between 3 and 5 %. This is sufficient to reduce the thermoplasticity to such an extent and to impart so much elasticity to the bitumen that weather-resistant road coverings, which can take up high shearing forces, can be obtained.

1.4.2.7. *Chewing Gum*

Special SBR latices, whose composition and production techniques are specified precisely by FDA, FCC, and BGA regulations, are coagulated by the addition of salts. The coagulum is washed and dried. The gum base is produced from the dried polymer, ester resins, microcrystalline waxes, and whiting by mixing in a kneader. Later, sugars or sugar substitutes and flavorings are introduced into the gum base. The chewing gum material is finally molded and packaged. Apart from different compounding, latices whose polymers have very low Mooney viscosities are used for bubble gum [32].

1.4.2.8. *Acrylonitrile – Butadiene – Styrene (ABS) Polymers (see also ⟶ Polystyrene and Styrene Copolymers)*

Polybutadiene latex is used as grafting base for ABS polymers. Styrene and acrylonitrile are grafted onto the polybutadiene by emulsion polymerization. The demand for latex in this area is very high. The consumers are raw material producers in the plastics industry.

1.4.3. ***Application on Substrates***

The use of latices on widely varying substrates is much more important in terms of quantity than production of rubber articles or functional materials.

1.4.3.1. *Paper and Cardboard*

Paper Coating [33] (⟶ Paper and Pulp, ⟶ Paper and Pulp, ⟶ Paper and Pulp). Demands are continually being increased on the quality of prints on paper and cardboard. Natural paper has an uneven surface. Cellulose fibers and fillers absorb printing inks to different extents, which leads to blurred print.

Paper and cardboard are coated to improve printability. An aqueous pigment dispersion, the paper coating color, is applied on one or both surfaces. A uniform smooth surface is thus obtained and printing can be carried out with perfect contours and as high a color reproduction consistency as possible. To ensure that the pigment layer adheres perfectly to the paper and shows optimum cohesion, a binder dispersion must also be added. These dispersions are now predominantly SBR latices or dispersions of polyacrylates, both types introducing carboxyl groups into the polymer. They are known as synthetic binders, as opposed to natural ones such as starch, casein, or other proteins.

The printability of the coated paper is determined mainly by the nature and quantity of the pigments, as well as by the binder(s). Other additives, such as dispersion aids, wet-strength agents, thickeners, optical brighteners, and dyes, are added as processing aids to control certain properties of the coating, principally printability, as well as processibility of the coating color on the coating machines.

The polymer dispersions must be compatible with one another and with co-binders, e.g., cellulose ethers, starch, poly(vinyl acetate), and poly(vinyl alcohol). These co-binders mainly affect the viscosity and water retention capacity of the paper coating color. This multisubstance system must meet all technical requirements. At the high speeds of modern coating machines the coating color is subject to extremely high shear forces, so all products must also be rheologically compatible. The quantity of latex dry substance based on 100 parts pigment is only ca. 10 – 15 %, to which ca. 0.5 – 6 % co-binder can be added.

Paper Impregnation. Masking tape is impregnated with NBR or SBR latices or polyacrylate dispersions to improve its strength, also when moistened with water or other solvents. The tape can then readily be removed from the masked surface, after painting or varnishing work. When used as packaging materials these tapes have increased strength even under unfavorable weather conditions.

1.4.3.2. *Carpeting (see also ⟶ Floor Coverings) [34]*

The latex consumption of the carpet industry is very high and, in terms of volume, about the same as that of the paper industry. In needle felt floor coverings and tufted carpets, the latex polymer applied is important for the durability of the floor covering. However, woven carpets are treated to give a sizing effect.

Needle Felt Floor Coverings (see also ⟶). Needle felt, whose surface can be structured, is produced from textile fibers with or without woven fabric support. The needle felt is bonded by lick-roll application on the underside or by full-bath impregnation with a latex compound, usually XSBR latex. In exceptional cases, acrylate copolymer dispersions are used. Vulcanization or other cross-linking agents are not added. The use of fillers is possible only in lick-roll application; otherwise, the colors would become hazy. The light and aging resistance of modern XSBR latices is so high that discoloration of the carpeting or premature aging through underfloor heating is not expected. Resistance to water and

shampoo is also achieved, giving an ideal overall range of properties.

Needle felts, which are thermomoldable in three dimensions, are used for floor linings in cars, for carpeting car boots, and for parcel shelves. Here a latex of a thermoplastic polymer is used, which can be molded at < 150 °C in order not to deteriorate the fiber material and still guarantee dimensional stability of the molded article at 90 °C. Special SBR latices with high styrene content in the polymer are employed.

Tufted Carpets (⟶ Floor Coverings – Carpet Properties and Performance). In the tufting process, mechanical bonding of the pile thread to the backing is so low that a latex coating on the backside is essential for perfect anchoring. Highly filled NR, or preferably XSBR latex, is used. Vulcanization or additional cross-linking is unnecessary (see above).

A straight backing, which then also forms the underside of the carpet, is filled with up to 300 % whiting, based on the latex dry matter. Precoatings, which are followed by a foam coating, contain up to 700 % whiting. For bonding the pile and at the same time laminating a fabric onto the back, a maximum of 300 % filler is incorporated into the latex.

In all cases mentioned, the filler is added directly to the latex; it does not have to be predispersed. Depending on the application system and the total solids content of the compound, the viscosity is regulated by the addition of a thickener. For better distribution on the backside of a carpet and in the loops of the pile threads (good filament binding), the latex compound is often slightly foamed. Foam weights of 500 – 1000 g/l are generally used, never lower ones.

Foam Backing. To increase the elasticity and sound insulation, tufted carpets are frequently coated with foam on the reverse side. This foam is compounded similarly to molded foams (see Section Molded Foams). Unlike molded foams, carpet foams are filled. The filler makes the compound cheaper and increases the weight per unit area of the carpet, which is important for perfect laying. High quantities of filler naturally reduce elasticity and increase compression set.

Besides sodium silicofluoride gelling (Dunlop process), ammonium acetate is also used for gelation in foam coating of carpets. The former allows filler quantities of 90 % maximum, the latter, up to 140 %. In addition a nongel foam coating process is also used. Unlike for molded foam or gel foam, sodium sulfosuccin(am)ate is added to the latex as a foaming aid which also prevents the foam from collapsing during drying. The combination and quantity of surfactant added are the only factors determining the foam structure and stability. Filler quantities up to 180 % are possible. A gelling agent is unnecessary. The dried combination of fatty acid soaps and sulfosuccin(am)ates is neither tacky nor greasy and therefore does not impair the quality of the foam layer.

Gelling of the foam or slight predrying of the surface (nongel) takes place under an IR field. Immediately afterward the foam is dried in a tenter frame and vulcanized.

Woven Carpets. Woven carpets and gripper Axminsters are constructed in such a way as to give them suitable end-use properties. The backside finishing, mostly with XSBR latices or vinyl acetate copolymer dispersions, essentially gives a variation in hand. The latices are generally processed with or without small quantities of fillers. The remaining processing corresponds to that of tufted carpets.

Carpet Underlays. Carpet underlays are used mainly under stretch-fitted tufted carpets with double backs or under woven carpets. They increase sound and heat insulation. Needle felt or nonwoven fabrics are sprayed with XSBR latices only at the surface, to improve the cohesion and abrasion resistance of the surface. *Foam underlays* correspond to foam backing of carpets. The foam is applied to thin carrier materials (e.g., spun bonded nonwoven).

1.4.3.3. *Shoe Materials [35]*

The shoe industry is not a direct consumer of latices but uses a large number of materials and adhesives made from them. Shoe parts made with the aid of latex are insoles, toe puffs, long counters, sock and side linings, inserts, and small foam parts. The shaft is fixed onto the insole, and the outsole is later mounted to the bottom. The toe puffs and counters give the tip of the shoe and the quarter box shape and rigidity. Small foam parts are used e.g., as heel lifts, and arch supports.

Insoles.
Cardboard Insoles. Cellulose sheet is impregnated with CR, XSBR, or NR latex, or their mixtures (depending on quality requirements), on a modified size press between the wet end and drying section, when it has a solids content of ca. 50 %. Latex precipitation in the pulp and subsequent sheet formation, instead of wet band impregnation, are also used. The finished cardboard is characterized by good dry and wet abrasion resistance. The rigidity achieved depends on the latex or latex mixture used. Antioxidants are added to the latices if this has not already been done by the latex producer. Zinc oxide is added to CR latex to achieve optimum aging resistance. Aluminum sulfate and sodium aluminate are added to the pulp to give a defined electrolyte content on the surface of the pulp fibers for successive precipitation of the latex particles.

All latices or latex compounds employed must be so stable or appropriately stabilized subsequently that they are not coagulated in the moist web of pulp by the electrolytes contained therein. During drying, which begins after impregnation, coagulation should take place so that polymer migration and thus delamination of the resulting cardboard is avoided. The polymer is not cross-linked or vulcanized, because the insole material must be moldable so that it can be adapted correctly to the contours of the shoe bottom. More than 50 % of the shoes produced have insoles made from this type of cardboard material, which is also used for other leather goods such as briefcases.

Needle Felt. Needle felt, which can also contain reinforcing woven fabrics, is impregnated with XSBR latices with high styrene content processed to form insoles for sport shoes or slippers. Fillers are added, depending on the requirements of the finished product. Vulcanization is not carried out. The stitch tear resistance of these textile articles is greater than that of insoles made from pulp. In addition the wet strength is higher and the water absorption lower than with pulp material. This is particularly important for flexible shoes.

Reclaimed Leather. Leather fibers obtained from vegetable and chrome-tanned leather clippings are formed into a web in the usual wet process on the Fourdrinier sieve. Generally NR latex, sometimes blended with high-styrene content SBR reinforcing latex or poly(vinyl acetate) reinforcing latex, is added to the pulp and precipitated on the leather fibers.

Chrome-tanned fibers contain sufficient electrolytes to bring about precipitation without other additives. For vegetable-tanned fibers the polymer of the latex is precipitated on the fiber by the addition of alum. Generally both types of fiber are used as a mixture. Vegetable tanned fibers increase the rigidity of the finished leather board, and chrome-tanned ones increase the softness. Vulcanization cannot be carried out because leather fibers are irreversibly damaged at temperatures of more than 80 °C. If the content of vegetable tanning agents (e.g., quebracho or mimosa) is high enough, antioxidants need not be added to NR latex, because these substances guarantee adequate protection against aging.

Leather board is used by the shoe industry mainly for making insoles, layered heels, out-soles, and long counters. It is also used as partition walls in leather bags. Particularly thick and impervious material is produced to make special containers (spinning cans), or it can — being flame retardant — be used in protective masks for electrical welders.

Shoe Stiffeners. Leather board is to a limited extent used as stiffening material. More commonly shagged cotton or rayon woven fabrics and thin spun bonded nonwovens are used as substrates for shoe stiffening materials. They are impregnated with highly crystallizing CR, or NR, XSBR, and polystyrene latex, SBR latex with a high styrene content, or their mixtures. The type of latex used depends on the shape of the shoe and the leather, and thus also on fashion. Thin leather and narrow shoe profiles require elastic toe puffs; thick leather uppers and broad shoe profiles require hard ones. Long counters are, in principle, always stiff.

The latex solid matter pick-up of the stiffener substrate is always more than 100 %. The deposited polymer not only hardens the stiffener material, but also acts as an adhesive in the mounting of shoes. Often, however, the impregnated material is additionally coated with an adhesive on one or both sides.

The stiffening material is cut to size; the edges are chamfered, where necessary, and the long counters are often — in the case of leather board, always — premolded in special workshops.

In shoe assembly, the stiffeners can be solvent or heat activated. Under the corresponding effect, these shoe parts soften and become tacky. In this state, they are inserted between the upper material and the lining, and subsequently mounted on the lasting machine. The non- cross-linked polymer applied as a latex here acts as both an adhesive and stiffening element.

Insoles, Inserts, and Small Shoe Parts. All of these are latex foam materials, and their production has already been described (see Sections Molded Foams and Carpeting).

Nonwoven Imitation Leather (see also ⟶). A nonwoven fabric made from fine, intensively needled fibers — preferably polyamide or polyester — with high apparent density, is used as the substrate. It is impregnated with an XNBR latex, which is rendered heat sensitive and vulcanizable. Sometimes a self- cross-linking NBR latex is employed. The latex compound is then coagulated in an IR field. Water-soluble substances can be removed by rinsing. Finally, the fiber – binder composite is dried in hot air and vulcanized.

This material, with its fine fibers intensively intertwined with one another and uniformly deposited binder agglomerates, has a structure very similar to that of natural leather. Like the latter, depending on the thickness of the material it can be split, buffed, sewn, and machine stitched.

NBR latices are used for imitation leather, mainly because of the grease, solvent, and plasticizer resistance of the vulcanized polymer. Elasticity properties are naturally also important. Besides zinc oxide, a small quantity of sulfur and an accelerator are employed as the vulcanization system for XNBR latices.

Nonwoven imitation leather is employed uncoated as heel grips and trimmings for sportsshoes, and coated as sock, quarter box and side lining, and occasionally as the upper material in shoes. It can also be used for leather bags.

Leather Finishing. Leather finishes consist of several layers of different polymer binders. The main components of base coats are dispersions of polyacrylates, polyurethanes, and NBR latices. Good adhesion to the substrate and between individual layers is a requirement of the finish, as are resistance to aging, dry, wet, and low-temperature flexing [36].

1.4.3.4. *Textile Finishing*

In the textile industry, aqueous systems are much easier to be applied and more versatile than those based on organic solvents. Latices are therefore very important.

Textile – textile or textile – foam laminates are produced by using either filled or unfilled latex compounds. Generally, latices of self- cross-linking or carboxyl- containing polymers are employed. The thickened latex compound is applied to the textile web with a doctor blade, and the second web is laminated onto it immediately with pressure rolls. This is followed by drying and thermal cross-linking.

To achieve air permeability of the laminates, the latex compound can be applied with a doctor blade as a thin foam layer, sprayed on, or lickroller applied in such a way that only the raised crossover points of the woven fabric or the peaks of the foam sheet are coated with laminating compound. This method naturally yields weaker laminates.

The *flocking of textiles* is usually carried out in an electrostatic field. The latex compound with a varying degree of filler is applied with a doctor blade to the textile to be flocked. The flocks are then electrostatically shot into this adhesive layer where they are anchored in a vertical position. Again this is followed by drying and thermal cross-linking. The product has

a softer feel if the adhesives applied are mechanically foamed.

Latex coatings are relatively rare. Examples are protective clothing (e.g., butchers' aprons from woven fabric), which are coated with vulcanizable NBR latex compounds, or fabrics for air mattresses, which are coated with vulcanizable SBR latex compounds. The use of NBR and polyurethane latices as tie coats for polyurethane transfer coatings is rather common.

Pile fabrics, such as velvet and plush, are frequently provided with a back sizing to increase pile strength. Self- cross-linking polyacrylate or ethylene – vinyl acetate (EVM) dispersions, or XSBR latices, are used here. The thickened, often foamed, latex is almost always applied by lick rollers, so that the softness of the pile article is minimally impaired. The quantities applied are kept as low as possible to maintain the appealing feel of the article. Examples are pile linings for parkas and plush covering for toy animals.

Base fabrics for emery cloth are finished with latex to achieve rigidity and dimensional stability. Also, through latex treatment a cloth surface is achieved that prevents too high a penetration of the resin applied to bind the abrasive materials. Penetrated resin is not available for binding the grain and impairs the strength of the woven fabric because of its high rigidity. Emery cloths must be water resistant, and often oil resistant, because they are in contact with drilling oil emulsions. Latices of self- cross-linking polymers are used, and NBR co- and terpolymers are the most suitable types.

1.4.3.5. *Textile Printing*

Polymer dispersions — particularly self- cross-linking polyacrylate, NBR, and SBR latices — are used as the pigment binder for textile printing. Good pigment- carrying and binding properties, perfect thickening characteristics, and high shear stability are prerequisites for a pigment binder. The print must be resistant to light, aging, washing, and dry cleaning.

Pigment printing systems are most commonly used in roller and rotary screen printing. In the former, because of the high working speed, enormous shear forces occur, which affect the printing pastes [37].

1.4.3.6. *Textile Finishing with Rubber Primer*

In rubber goods such as tires and conveyer belts, the construction materials rubber and reinforcing textiles have to adhere perfectly to one another. This is maximized by dipping the textiles in a rubber primer. The woven fabric or cord threads are impregnated with an adhesive compound, which in principle consists of **r**esorcinol –**f**ormaldehyde precondensate and **l**atex (RFL-dips, see also ⟶ Rubber, 4. Chemicals and Additives – Adhesion of Rubber to Reinforcing Materials).

Emulsion polymers of butadiene, styrene, and 2-vinylpyridine are used mainly as the latex component. The content of 2-vinylpyridine in the polymer is between 7.5 and 15 %. This content is critical for optimum adhesion. To achieve adhesion of “nonproblematic” substrates, such as rayon cord to rubber, latices with low 2-vinylpyridine content are employed, or the quantity of this polymer component is intentionally reduced by blending with SBR latex. However, polyamide cord requires latex with a high 2-vinylpyridine content. In exceptional cases, instead of pyridine – styrene – butadiene rubber (PSBR) latex, NBR or CR latices are used. For instance, NBR latex is used for the reinforcing fabric of NBR conveyor belts, and CR latex for the reinforcing threads of CR V-belts.

In the impregnation process, only the outer filaments (ca. 2 or 3) are wetted and bound together by the dried resin – latex film in order to maintain the inner flexibility of the cord. After impregnation the textiles are dried and, if this has not already been done, are thermoset in hot air to increase their dimensional stability [38].

1.4.3.7. *Gaskets*

Flat gaskets may or may not be reinforced.

Reinforced gaskets are generally produced ready for fitting according to construction drawings, and nonreinforced ones as sheetings from which individual seals can be die cut. Woven wire or metal band cloth and perforated, so- called spiked metal sheets are used as reinforcing materials. Gaskets made from spiked sheets are always produced ready for fitting. For example, the reinforcing material is coated on both sides with a mixture of mineral fibers, filler, rubber, vulcanizing chemical, and antioxidant, and then vulcanized in a press. The mixture is produced in an internal mixer. NBR latex is used as the rubber component because of its high resistance to heat, oil, and fuel. Slight swelling in the medium which is to be sealed, increases the tightness of the gasket. If this effect alone is predominant, then NR and SBR latices can also be used. The polymer employed is first swollen by addition of toluene to the latex and then mixed with other ingredients in the internal mixer.

Compressed mineral fiber sheets (It plates) are built up in layers on a calender. Two-ply gaskets can be produced in this way. The mixture of mineral fibers, filler, swollen NBR latex, vulcanization agents, and antioxidants is applied to the hot calender rolls. The material is thus formed into sheets and any solvent and water remaining are evaporated. For all gasket materials mentioned, semiultraaccelerators are used — in contrast to the usual latex processing — so that premature vulcanization in processing the mixtures is avoided.

Low-density gaskets are produced on paper machines from both mineral and cellulose fibers. The latex used as a binder is mixed with vulcanization agents (ultraaccelerators, antioxidants, and sometimes emulsifiers for stabilization), diluted, and added to the fibrous pulp in the mixing vat. On mineral fibers the mixture precipitates quantitatively because of the surface charge of the fiber, often without any additives. To achieve optimum properties the surface charge of the cellulose fibers is reversed with the usual retention agents before the latex compound is added to the pulp, so that the latex compound later precipitates perfectly on the fibers. The remaining processing corresponds to that used in paper production. The final step is vulcanization, which takes place in hot air or with contact heat.

NBR latices are generally used because of the oil, gasoline, and heat resistance required. In special cases, CR, NR, or

SBR latices can be used.

1.4.3.8. *Nonwoven Fabrics (see also, ⟶ Nonwoven Fabrics) [39]*

Nonwovens are used for interlinings in the apparel trade. They are also used as coating base, cover stock for hygienic articles, hospital and camping linen, filters, waddings and quiltings, insulating materials, reinforcements, abrasive and polishing disks, draperies, upholstery materials such as rubberized hair, geotextiles, wipers, etc.

These fabrics are, in general, no longer bonded by latex impregnation, but by other techniques. Latex treatment is often applied to achieve special effects (e.g., rigidity and resilience in the case of linings). Because of better decomposition in composting, latex-bound nonwoven fabrics for cover stocks are gaining more importance than thermally bonded ones. For some abrasive nonwovens, spraying with latex not only bonds the fibers to one another but also fixes the abrasive grit on the bonded fiber.

Rubberized hair for car seats is bonded with vulcanizable SBR or NR latex compounds and, if flame resistance is required, with CR latex compounds. The latex mix is sprayed onto the fiber mat and dried but not vulcanized. The web material is later cut to size, placed in molds with varying packing density, and vulcanized in the closed molds.

Wiping cloths made of nonwovens are partially bonded either thermally or by printing with polymer dispersions if only a short lifetime is required. Heavy-duty wipers for floors, windows, and cars are bonded more intensively.

For high-performance *window and car wipers*, the wiping effect is particularly important. This involves the strong adhesion to smooth surfaces (e.g., window panes) shown by natural chamois leather. These cloths function by completely wiping away water, as windshield wipers do, and absorbing it. Also, as with windshield wipers, the effect described is achieved through thin rubber lamellae. A vulcanized latex foam has many such lamellae in the form of cell walls of the foam pores. Relatively thin, needled, nonwoven fabrics, which are generally preimpregnated with a foamed latex compound, are coated on both sides with a thin latex foam layer. Because of the resistance to oil, grease, and to some extent, fuels, which are absolutely essential for these cloths, the use of NBR latices is preferable.

For *floor wipers* such a wiping effect is precluded because they should slide smoothly over the floor and absorb the cleaning water, which must then be wrung out easily.

Needle-punched nonwovens made from cellulose fibers are coated on both sides with foamed latex compounds. The very thin foam layer gives the article good abrasion resistance, without impairing its capacity to absorb or release water. Both vulcanizable and self- cross-linking NBR latices are used for these cloths.

[Top of Page]

2. Solid Rubber Processing

Jochen Schnetger

The production of rubbery materials with industrially useful properties from solid rubber involves the incorporation of a range of additives (⟶ Rubber, 4. Chemicals and Additives). The latter critically affect the properties with regard to process technology and permit cross-linking or vulcanization. To achieve a sufficiently high and uniform property level of the rubber articles produced, homogeneous distribution of all additives in the tough rubber matrix is necessary.

The raw compound is then processed further and molded by different procedures such as calendering, extrusion, pressing, injection molding, or coating processes, and vulcanized through further energy input. Cross-linked structures are thus built up, which convert the rubber blank into a rubber-elastic material. Processing is generally carried out in internal mixers, less frequently in open mills.

2.1. Internal Mixer (Kneader) [40-47]

2.1.1. *Construction*

Processing of rubber compounds in the internal mixer is a batch process. The important components are the ram, mixing chamber, kneading rotors, and the downward-opening drop or hinged door (see Fig. 1). The construction of the kneading rotors is very important for mixing intensity.

Figure 1. Schematic of an internal mixer with ram

a) Ram; b) Ram cylinder, c) Suction; d) Hopper; e) Mixing chamber; f) Kneading blades; g) Saddle

In principle, two different systems can be found (see Fig. 2):

1. *Tangential rotor systems with friction* (i.e., different peripheral speed of the kneading rotors whose ratio is defined as friction; ca. 1: 1.1). Mixing is performed between the blades, and between the blades and the mixing chamber wall.
2. *Intermeshing rotor systems without friction*, in which the rotor wings intermesh. Because of this intermeshing the rotors cannot run at different speed and friction due to the rotor blades is thus not possible. However, friction results

from different peripheral speed of the wings or screw blocks and the rotor core. This allows a more intensive mixing process compared with the tangential rotor systems.

Figure 2. Kneading blade systems

A) Tangent system; B) Interlocking system

a) Ram; b) Cooling; c) Saddle

The advantages of the tangential rotor system are:

1. Good pulling-in action
2. Greater useful volume
3. More rapid emptying

The intermeshing rotor system has the following merits:

1. Rapid mixing
2. Good temperature control
3. Lower dumping temperature
4. High energy input in the shortest time
5. Good filler dispersion [ethylene – propylene – diene (EPDM), etc.]

2.1.2. *Mode of Operation*

After automatic or manual filling of the internal mixer with the compounding ingredients, the hopper is closed by lowering the ram. Ram pressures of 4 to 12 bar are applied.

The ram holds the material being mixed between the blades, and between the blades and the chamber wall, during mixing — thus enhancing mixing efficiency considerably. The ram is normally operated pneumatically. However, models with hydraulic control have been produced.

At the base of the mixing chamber is a *hinged (drop) door*, whose flaps can be closed hydraulically by a motor. The sliding door systems used previously resulted in emptying times that were too long and are no longer used. The kneading rotor systems and the inner wall of the mixing chamber are protected by electroplating against too rapid abrasion. Nevertheless, the chamber volume must be checked at least once a year, so that any changes can be dealt with immediately. Uniformly good dispersion of all compounding ingredients is then guaranteed only if the full volume, once optimized, is not altered.

Driving Mechanisms and Power. Internal mixers are equipped either with electrical driving mechanisms having constant speeds, or one or more fixed speeds, or with variable driving mechanisms and continuously variable speed control of the rotor system. Automatic mixer controls require continuously variable speed control. To deal with very high torques, the unidrive mechanism is generally used (branching of two motor shafts from the gear box). The mechanism is driven by a d.c. motor.

The driving power required to achieve the necessary mixing and shearing action is at least 6 kW, and usually 10 kW per liter.

Heat Removal. Depending on the plasticity of the material being mixed, considerable heat of friction can be produced in the mixing process, which must be removed effectively. This is achieved by cooling the entire working surface, the mixing chamber, the rotor systems, the ram, and the drop door. A reproducible and established temperature course during mixing is extremely important. The temperature of the cooling water and the flow rate must therefore be kept constant. The mixer may also have to be set at a given temperature before the beginning of the mixing cycle (i.e., to thermostat it and avoid water condensation or undesirable temperature jumps on starting up with the first batch).

Metering of Components, Measurement and Control. Modern mixing lines are equipped with *control systems*, which include weighing systems (see Fig. 3). A reproducibly optimized compound quality and an economical production process can be guaranteed only by computerized systems. A basic prerequisite for this is exact metering of all additives. This includes automatic weighing from day tanks that are filled from large silos; computer- controlled, sequenced hand weighing (belt weigher for filling the hopper); and the predominantly non-sequence- controlled weighing of small components. Permitted deviations in, for example, the 100-kg region are ± 0.1 kg.

Figure 3. Internal mixer production line

MC = Master computer; L = Line computer; P = Printer; MC/CD = Master computer and control disk

The control of automatic balances is carried out by additive weighing and control of deviation after each component. The

dosage time and emptying (0-point) are monitored. The belt weigher filling the hopper is connected with a preset weight limit. Total balance results are shown by a monitor with component and tolerance data.

Plasticizers are injected through the side of the chamber wall with the ram closed after the weighing process. Small components, provided they are not weighed by hand under sequence control, are added via the belt weigher. Automatic weighing devices for small components function well.

The charging operation, the movement of the ram (aeration, cleaning), balance readings, speed changes, and emptying are all controlled. Regulation parameters include the cooling water temperature, the temperature of the bulk of the material, and the energy (torque). The last two can be varied by the rotor speed and the ram pressure. Changes in temperature or energy absorption can be controlled by the variable speed of the motor, whereby the given set points for time and temperature or energy input are compared with the actual value, and adjusted by means of the speed within the given tolerance limits. The control and regulation of the mixer, weighing system, other peripheral machines, and alarm indicators; data acquisition from field instruments; production monitoring; etc., are all carried out by the line computer assigned to each production line. Process data are processed by a master computer, which controls formulation, plans production, balances material, carries out documentation of production and process data, and is connected to a central computer (host). Desired process parameters can be stored in the master computer, which then controls the line computer for the mixer and the subsequent machines in the mixing line. These data can also be stored in individual line computers, which then report process parameters back to the master computer.

2.1.3. *Compounding*

Before compounds can be produced in the internal mixer, the *degree of filling* and the batch weight necessary for it must be determined from the filling factor. The filling factor is determined by the supply company in preliminary experiments. Depending on the compound, the degree of filling must, however, be optimized in an individual case for the actual operation. Internal mixers are operated underloaded, with reference to the volume of the chamber. Intermeshing systems (see Section Construction), should be filled even less than tangential systems to achieve good compounding results. Filling factors are 0.7 – 0.9 for tangential and 0.6 – 0.7 for intermeshing systems. The degree of filling can be based on both the mixing chamber volume and the so- called useful volume. On quoting the degree of filling the volume on which it is based must be given.

$$\text{Degree of filling (in\%)(chamber volume)} = \frac{\text{Batch weight} \cdot 100}{\text{Compound density} \cdot \text{chamber volume}}$$

$$\text{Degree of filling (in\%)(useful volume)} = \frac{\text{Batch weight} \cdot 100}{\text{Compound density} \cdot \text{useful volume}}$$

$$\text{Useful volume} = \text{Chamber volume} \cdot \text{filling factor}$$

$$\text{Batch weight} = \text{Chamber volume} \cdot \text{filling factor} \cdot \text{compound density}$$

Important factors affecting the quality of a compound are the degree of filling, the mixing time, the temperature of the bulk material, the speed of the rotor, and the ram pressure.

To be able to incorporate all additives into the rubber matrix, the raw rubber must have a viscosity that is suitable for processing. This is the case for synthetic rubbers, which have a wide range of viscosities, and for specially treated natural rubbers [constant viscosity (CV) grades]. Natural rubber must, however, generally be degraded first (masticated) (⟶ Rubber, 4. Chemicals and Additives – Peptizers). *Mastication* is carried out with the addition of peptizers in the internal mixer or sometimes on the mill. The mastication cycle in the internal mixer lasts 3 – 5 min, depending on the degree of degradation desired.

In a classical mixing operation the rubber, which has a viscosity suitable for processing, is either charged to the open internal mixer hopper via the belt weigher in whole bales (25- and 33.3-kg bales) or cut using a rubber cutter. After closing the hopper and pushing in the ram, the material is plasticized briefly, the ram is then raised, and the filler, plasticizer, antidegradants, stabilizers, or processing aids are added according to a predetermined time cycle. The bulk temperature can reach 180 °C, depending on the viscosity of the raw compound. The mixing time for the production of this *first batch* (basic compound) is ca. 2 – 5 min.

At the end of the mixing time the batch is discharged and shaped in the downstream equipment (see Fig. 3), cooled, and stored. Generally, after 24-h storage, accelerators and cross-linking agents are added in a second mixing stage (*two-stage mixing process*). The temperature of the compound must not exceed the cure onset temperature of the now mixed vulcanization system in this final mixing process, and is generally between 100 and 120 °C. The second, final compounding stage is also sometimes carried out on mills. Since the mixing temperatures for the batch and final compounding are very different, batch and final compounding mixers are used separately for reasons of capacity.

Compounds for highly dynamically stressed articles (e.g., tires) must be mixed very carefully to achieve optimum dynamic load- carrying ability. For this reason, particularly in the tire industry, mixing processes with *up to four stages* are used. For the production of technical rubber goods, two-stage processes, and sometimes one-stage, are usual. In *one-stage processes* accelerators and cross-linking agents are added in the final third of the mixing cycle. In this type of mixing the bulk temperature must not exceed the cure onset threshold of the accelerator system added. In addition, this type of mixing naturally requires the use of accelerator systems that are safe for processing.

The *upside-down process* is a variant for attaining high shearing forces rapidly. Here, fillers, antidegradants, stabilizers, or processing aids are charged first and, after a short premixing period, the raw rubber is added to the internal mixer. This mixing method is frequently used for special rubbers, such as EPDM, or rubber blends with polybutadiene. It is also used when very high quantities of filler are required. If conventional mixing were used in such a case, crumbling of the initially

compact rubber matrix would result, and the crumbly material could only build up sufficient shearing forces to form a compact compound after long rotation times, if at all. Mixing is carried out for a predetermined time and at a predetermined temperature or following a predetermined energy diagram.

Generally, the mixing time for the batch must be long, since too short a cycle time results in insufficient filler dispersion, which is virtually impossible to remedy in further processing steps.

After the mixing stage is finished the hot mixed material is discharged by rapid opening of the drop door. A *mill* situated directly below the hopper is used as a receiver. Here, the unshaped lumps of compound are rolled out to form sheets and are transported on a conveyor belt to a second mill with a stock blender (see Fig. 3) for further homogenizing and intensive cooling. The rubber sheet is then threaded into a batch-off machine (see Fig. 4). This machine coats the still warm sheets with external lubricants, cools, and stacks them. The sheets are passed through the machine in endless loops on cross-bars of a double- chain conveyor. They pass through a curtain of external lubricant spray and a blowing device fitted with ventilators to remove residual moisture from the loops and cool the sheets further. They are deposited in loops (wigwag system) or in strips, which are cut with circular knives before deposition. Coating with release agents lowers the surface tackiness of the raw compound to such an extent that the deposited sheets can be separated easily from one another for further processing.

Figure 4. Batch-off machine

a) Knife; b) Gripper; c) Cooling; d) Lubricating agent; e) Input; f) Sheets; g) Lubricating agent bath; h) Wigwag stacking

Instead of the mills, special *extruders* can also be used. Here the compound falls into a large hopper equipped with rams as plugging devices. Depending on the desired form of the raw compound, the extruders can produce sheets or pellets (special extruder heads, pelletizers). Strainers allow the removal of foreign bodies. *Special extruders* are required if large internal mixers are used, as in the tire industry. The very high batch weights used here (up to 500 kg) can no longer be managed by mills in short processing cycles. Outside the tire industry, *strainer-extruders* and *pelletizers* are being increasingly introduced as downstream machines for rubber processing. Granulates or pellets can also be produced in batches on band granulators, which are located downstream of the batch-off machines. Granulates are more expensive to produce but allow further automatic processing steps in extruders or injection molding machines. With technical rubber goods a completely continuous process for the production of compounds — premixing in the internal mixer and processing in subsequent shaping extruders with the formation of strips or pellets — has not proved successful since temperature control, particularly in the case of sensitive vulcanization systems, is extremely difficult. In addition, changing from carbon black-filled to white compounds is extremely difficult because adequate cleaning of the equipment is nearly impossible. Sometimes such continuous operations are used in the production of cable compounds.

2.2. Open Mill [40], [41]

Roll mills are used widely in rubber processing. Their importance as mixers for the complete production of rubber compounds is small compared to the internal mixer. Nevertheless, they are still indispensable as downstream machines to the internal mixer (see Fig. 3), as prewarming roll mills for warm-feed extruders, as feeder roll mills for calenders, for mastication of natural rubber, for breaking stiffened compounds, and for the production of reclaims (refiner mills). They are sometimes also used for the final mixing of raw compounds in the second mixing stage, particularly when small quantities of compound or limited amounts of compounds with light fillers are produced. In the laboratory, they are employed for the production of compounds for quality control using rapid tests and for general compounding development (laboratory mills) as well.

2.2.1. *Construction*

An open mill consists of two parallel, horizontal, chilled casting rolls, which are fixed into gliding or rolling bearings, and rotate in contrary directions at different speeds (see Fig. 5). The front roll turns more slowly than the back roll.

Figure 5. Construction of rubber mill

a) Rubber compound; b) Vibrating trough

v_1 = speed of front roll; v_2 = speed of back roll; $v_1 < v_2$

Roll mills can have constant speeds and fixed friction or controllable speeds and continuously variable friction. The machine is predominantly driven electrically (d.c. motor), or sometimes hydraulically. In modern mills, the rolls run on rolling bearings. The necessary driving power is 2 kW per liter of compound. Industrial roll mills have a friction of 1: 1.1 to 1: 1.2. Frictions of 1: 1.3 are also possible.

The dimensions vary from 100×225 (diameter × roll length in mm) to 200×450 for laboratory roll mills, and from 300×700 to 850×3000 for industrial machines. The rolls can be heated and cooled. While mixing, the rolls are generally cooled intensively by cooling channels below the roll surface (rolls with holes on their periphery, see Fig. 6).

Figure 6. Roll with peripheral holes

a) Cooling agent; b) Cooling channel; c) Roll

2.2.2. *Mode of Operation*

Mills operate with independent cooling and heating systems. The roll nip is regulated by moving the front roll. Two material guides are fixed on the sides and prevent penetration of the rubber compound into the bearings. Additional homogenization and cooling of the compound are achieved by setting up a stock blender. A *stock blender* consists of a pair of draw rolls, fixed above the front roll, to which the sheet is fed by the backward and forward motion of the contact roll (see Fig. 7). The sheet then passes back into the roll mill over a guide plate.

Figure 7. Mill with stock blender

a) Stock blender; b) Guide plate; c) Compound; d) Mill; e) Compound sheet; f) Guide roll

If the pressures built up in the roll nip are too high, the nip is automatically raised either by pressure plates with a preset breaking point or by pressure sensors that produce a corresponding signal. Mills can be operated almost automatically by memory-programmable sequence control. This clearly improves production safety, which is limited by the need for manual servicing.

Cracking and Refining Mills. In the rubber processing industry, so- called cracking and refining mills are used as well. *Cracking mills* with corrugated surfaces and high friction (1: 1.78, 1: 3.24) are used to break up waste, old rubber, and hard compounds. *Refiner mills* with high friction (1: 2.0, 1: 2.50) and a narrowly fixed roll nip are used mainly in processing reclaims.

2.2.3. *Compounding*

In the mixing process the material to be mixed is drawn into the roll nip. This requires sufficient static friction between the raw rubber and the surface of the two rolls, which rotate with friction. Because of this friction, different forces act on the compound being drawn through and continuously shift the particles toward one another. Compacting then occurs in the roll nip. If the rolls were to run without friction, the material would be compacted inefficiently. The different rates at which the material is drawn through also make the rubber head on the roll nip turn, and thus contribute to homogenization of the compound. The compound is finally homogenized by manual cutting and reintroduction of the sheet formed into the roll nip. Use of the stock blender aids this process (see Fig. 7). The excellent mixing action of the mill is related to the fact that very intensive cooling is possible due to the large surface area; thus, high shearing forces can always be introduced.

The *mixing procedure* for the production of a rubber compound on the mill is analogous to that in the conventional internal mixer. Mastication of natural rubber is effected either purely mechanically or by using peptizers. Rubber bales must be broken up in the cutter before being introduced onto the mill. The roll nip is made wider with increasing use of additives so that the necessary rolling material head is maintained until all compounding ingredients are mixed. Otherwise, an ineffective, “dead” head is formed, which does not move and cannot contribute to the mixing operation. Only when a closed rolled sheet passes around without tearing, is the roll nip contracted to a predetermined width. The compound is homogenized by manually cutting the sheet, rolling it out, and passing it through again; it is then cooled. Finally, the sheets are removed from the mill, dipped in release agent solution, and hung to dry.

2.2.4. *Prewarming*

If compounds are stored, they stiffen with time. For charge calenders or warm-feed extruders, and in certain cases cold-feed extruders also, the sheets must be plasticized again on the mill and warmed. A strip is then cut from the sheet turning on the front roll with a pair of circular cutters. This strip passes continuously from the mill into the extruder or calender. Compounds without accelerators are also stored and are then mixed with the cross-linking agent and vulcanization system during warming.

2.3. Pellet and Strip Feeding [40], [48]

Processing of ready-mixed *pellets* (rectangular with ca. 8-mm sides) allows automatic feeding of extrusion and injection molding machines (vibration channel, spiral vibrating conveyor, suction conveyor system, dosage via a balance). Well-prepared pellets pass uniformly into the feed screw of the extruder, so that the danger of pulsation is decreased significantly. In principle, several batches of pellets can be homogenized well in drum mixers. The correct dosage of the powdery release agent (talc) is important for processing. On overdosage the pellets are drawn into the screw inefficiently and smear, which can lead to pulsation of the extrudate. Too little powder promotes the tendency to bridge in the feed hopper, bringing about irregular feeding and pulsation of the extrudate. The talc should be dosed automatically, and excess shaken off or removed by air classifiers. The addition of external lubricants in liquid form can lead to trapped moisture, which causes porosity in the extrudate. Irregular feeding into the screw is also caused by differing pellet sizes. If pellets are produced by band granulators, the attachment of a sieving device is recommended. For very soft compounds the granulate has a strong tendency to bridge, while strips tend to tear. Granulate production requires additional investment, which makes the process more expensive than strip production.

On *strip feeding*, the dimension of the strip must be matched to the width of the drawing-in nip of the particular machine. Splicing leads to faults in strip feeding. Constant surveillance is necessary (e.g., danger of tearing, see above). Processing very hard compounds (>80 Shore A, ML4>100) as strips is virtually impossible. Strips of soft compounds also tend to stretch, leading to irregular extruder feeding.

The possibility of automation and the uniform operating process are advantages of pellet production.

2.4. Production of Sheeted and Reinforced Rubber [40], [49], [50]

2.4.1. *Calenders (see also* ⟶ Plastics, Processing – Rolling and Calendering*)*

Calenders are used to produce raw rubber sheets and for frictioning or coat reinforcing materials (fabric or steel cord). In special cases they are used for the production of profiles or profiled sheets (profile calender). The calender consists of two to four rolls, which are made either from chilled cast iron or from heat-treated steel. In modern machines the rolls are fitted with roller bearings in the calender frame (connecting links), bored on the periphery, and equipped with heating and cooling devices and with independent feedback control systems. The usual lengths and diameters of the rolls vary from 1250 to 2500 mm and 500 to 900 mm, respectively. The rolls are driven individually by d.c. motors, and continuous adjustment for different friction is possible. Since the roll nip must be adjusted precisely to maintain the exact thickness of sheeting or the raw compound covering of the fabric or steel cord, very accurate testing of the nip width must be carried out. Roll feelers located on the roll pins and connected to each other by a resistance bridge are used for this. Any change in distance results in a change in resistance, which is then recorded as an electrical signal at the control desk and visualized digitally there. Modern calender machines — including peripheral devices such as feed-roll-mill-extruders and doubling machines — are run by programmable control systems. Temperature, roll nip adjustment, friction, roll velocities, skew mounting (slope adjustment), and roll bending (see below) are controlled. Measuring devices continually test the thickness of the calendered sheet (examples are devices for measuring weight per unit area by transmission reflection, electronic path-measuring systems, laser probes, or pneumatic sensors). The measuring systems can be equipped with controlling devices that, on deviation from set points, send adjustment signals to the skew mounting or roll bending instruments. Calenders differ and are named according to their construction (see Fig. 8).

Figure 8. Types of calender construction

In processing rubber compounds, high pressures can arise, which result in bending of the rolls. This in turn gives inexact and varying thickness of the sheet or coating. To give a uniform thickness of the sheet or coating, the calender rolls can be cambered or crowned (i.e., shaped like a double cone, Fig. 9). The result is that the nip is straight, and the sheet thickness therefore uniform, when the rolls are under pressure. However, the roll geometry is then suitable only for particular operating parameters such as calender speed, sheet thickness, viscosity of the compound, and roll temperature. Fixed crowning severely limits the range of use of a calender and is therefore rarely used. The state of the art is represented by variable processes for *skew mounting* (slope adjustment) and *roll bending* (see Figs. 9 and 10) to compensate for the bending of the calender rolls under load. In the roll bending process a hydraulic pressure is exerted on the extended roll pins to compensate for the pressure caused by the compound in the roll nip. Crowning can thus be varied by these measures. The skew mounting can be ± 25 mm and the roll bending ± 0.15 mm.

Figure 9. A) Crowned rolls (nip straight under pressure); B) Cylindrical rolls (nip broadening under pressure); C) Skew mounting; D) Roll bending

a) Supplementary bearing; b) Bearing; c) Hydraulic cylinder

Figure 10. F calender with skew mounting and roll bending

a) Roll 2 with roll bending; b) Rolls driven via universal-joint propeller shafts (d.c. motors); c) Rolls 2 and 3 coupled by gear bair for uniform speed during coating on both sides; d) Rolls 1 and 4 can be skew mounted; e) Roll 4 (or 2) guiding roll for doubling machine; f) Pressure roll; g) Calender speed 1: 10 adjustable, friction (max.) in one nip 1: 2

Two-roll calenders are used predominantly in combination with extruders (extruder-roll-head, extruder-roll-die machine, see Section Sheet Production in the Extrusion Process) or as underrubber calenders (coating tread strips with rubber cushioning) and in the low-temperature coating of steel cord. In the rubber processing industry, *three-* and *four-roll calenders* are used most frequently; the preferred four-roll calenders are of F- and L-type construction.

To draw sheets, F calenders are frequently used, in which the upper roll nip is charged with material. The L calender, used for drawing sheets and also as a laboratory calender, has the advantage of favorable feeding possibilities because of the rolls situated underneath. Calenders can be charged with prewarmed rubber compound by using roll mills with strip drawing or extruders. Z calenders are often used in the tire industry. These calenders are relatively small; the roll bending affects only one roll nip, and all roll nips are readily accessible.

2.4.2. *Calendering Process*

Drawing Sheets — Doubling (Fig. 11). Calendered sheets should have smooth, shiny surfaces and be drawn without blisters. Correct roll thermostatting is very important for surface quality. If the temperature is too low, cold spots are formed on the calender surface; if it is too high, blisters can form. In addition, the roll head of the compounding material must be kept to a low diameter in the roll nip and must rotate in one direction to prevent blister formation. Choosing the correct roll friction is necessary here. During drawing of sheets a certain forced orientation of the rubber molecules (calender effect) occurs, which, after release of the drawing force, leads to shrinking. Shrinking can be controlled by fixing the velocity of the take-off conveyor, the cooling drum, and the take-up roll. Shrinkage can also be minimized by adjusting the compounding formulation (medium-active fillers; for natural rubber, sufficient mastication; use of pre- cross-linked rubbers). Production of thicker sheets by passing several rubber sheets over one another in the calendering operation is called doubling. Sheets are doubled up to 6 or 8 mm (see Fig. 11). Thicker sheets can be obtained by warm – warm doubling (combining two warm components), warm – cold doubling (doubling a compound sheet under a finished cold sheet) and cold – cold doubling (doubling an already finished compound sheet from a roll).

Figure 11. Drawing sheets and doubling

a) Rubber compound; b) Doubling band

Frictioning (Fig. 12). In frictioning, a stored fabric is run in the calender and rendered adhesive by mechanical rubbing with a soft rubber compound having good surface adhesion. The fabric is then ready for use as a reinforcement in rubber articles. The rubber compound is fed into the middle roll as a closed band. Roll 2 turns faster than roll 3 (see Fig. 12). The friction is 1: 1.2 – 1: 2.0. Synthetic fabric must be predried and impregnated. Fabrics can be frictioned either on one side or, via a second operation, on both sides. The load on the fabric is very high in the frictioning process. More frequently, therefore, the fabrics are dipped, particularly when the fabric structure is very dense. Frictioned or dipped fabrics are used as reinforcements in conveyor belt, V-belt, and tire technology.

Figure 12. Frictioning of fabrics

a) Rubber compound; b) Fabric; c) Frictioning of fabric: $v2 > v3$; v = roll speed

Coating Fabrics and Steel Cord. Frictioned or dipped fabric or steel cord must be coated with a compound layer of defined thickness for further processing (e.g., in tire or conveyor belt production), so that further processing steps (i.e., construction with other compound sheets to give blanks) can be carried out accurately and rapidly. The reinforcement can be coated with rubber compound on one or both sides.

Warm Coating (Fig. 13). The warm compound is pressed onto the fabric or steel cord as it runs in. When coating endless cord, the threads of bobbin creels are drawn into the calender. Fabrics are fed out from a fabric storer. For coating on both sides, a four-roll calender must be used. Here, a second rubber sheet is drawn in the third roll nip (see Fig. 13 B, C).

Figure 13. Warm coating — one and both sides (fabric – steel cord)

A) Warm coating on one side; B) Warm coating on both sides; C) Warm coating of steel cord on both sides

a) Rubber compound; b) Fabric; c) Steel cord

The thickness of the layer of the drawn sheets can be adjusted to exactly ± 0.1 mm by skew mounting and roll bending. This is extremely important, particularly for the production of high-value radial tires. Unlike the low-temperature coating process the machine can be operated at high velocities (with parts for passenger car tires, ca. 30 m/min; with parts for truck tires ca. 15 – 20 m/min). In addition, in the warm- coating process, good penetration (i.e., good flow of the coating compound around the threads of the cord of the reinforcement) is achieved. Good penetration contributes significantly to rubber – cord adhesion, in particular to steel cord adhesion in dynamically stressed articles such as tires.

Low-Temperature Coating (Fig. 14). The low-temperature coating process is cheaper than the warm- coating process with respect to the machinery involved (two-roll calender), but it is not as productive and has disadvantages in terms of penetration. Servicing the machine is simpler, since the tire cord is kept in the middle of the calender rolls by the preprocessed, uniform-thickness calendered rubber sheets. Low-temperature coating machines must be operated slowly (speed ca. 50 % less) to achieve sufficient coating of the cord.

Figure 14. Low-temperature coating of steel cord on both sides

a) Rubber sheet; b) Steel cord

Skim Coating (Fig. 15). If fabric is to be coated or frictioned with relatively hard, dry compounds, working with uniform roll velocities has proved successful [v (roll 2) = v (roll 3)]. Skim coating can take place on one side or both by using a second operation.

Figure 15. Skim coating with uniform roll speeds $v_2 = v_3$

a) Rubber compound; b) Fabric

Profiling (Fig. 16). For profiling three- or four-roll calenders are used, which have a roll with an exchangeable profiled cylinder. The applications include tire parts that are difficult to extrude, profiled sheets, bicycle tire segments, etc.

Figure 16. Profile roll calender

a) Rubber compound; b) Profile roll

2.4.3. *Sheet Production in the Extrusion Process*

Extruder-roll-head machines (Fig. 17) consist of combinations of extruders with a broad roll extrusion head and two-roll calenders. The rubber extruder can be designed as a warm- or cold-feed extruder. Modern extruder-roll-head machines are equipped with pin cylinder extruders. Rubber sheets can be extruded to a width of 2400 mm and a depth of 1 – 25 mm. Here, the rolls operate at the same velocity.

Figure 17. Extruder-roll-head machine

a) Pair of rolls; b) Broad extruder head; c) Extruder; d) Actual pressure; e) Pressure set point; f) Pressure control system

Extruder-roll-die machines are constructed very similarly to extruder-roll-head machines. These units, set up downstream from the internal mixer, with a differently constructed extrusion head, are used as shaping calenders for the rubber sheet.

The one-roll-head extruder is another type of construction for the production of rubber sheets. Here an extruder is combined with a roll that is flange-mounted at the head. Sheet widths up to 500 mm at 300 mm roll diameter can be drawn.

2.4.4. *Vulcanization of Rubber Sheets*

The vulcanization of the sheets, which are taken up from the calender in the form of rolls, can occur batchwise in heating chambers or autoclaves.

Continuous Vulcanization. For continuous vulcanization a rotation process is available. The rotation vulcanization machine (see Fig. 18), also known as rotocure (in German-speaking countries the name AUMA = Automatische Matten Maschine is used), consists of a drum that can be rotated and heated. The rubber sheet is pressed onto the drum with a steel band or a rubber- coated sliding band. A subsequent heating channel mounted on the machine stand can also be used. The discharge capacity is clearly increased by this measure.

Figure 18. Rotation vulcanization machine

a) Additional heating; b) Steel band; c) Vulcanized rubber; d) Take-up reel; e) Fabric; f) Back cloth; g) Raw rubber sheet

The rotocure can be connected in series to an extruder-roll-head machine (completely continuous operation) or used behind a calender. Preprocessed articles, such as conveyor belts, are also vulcanized on the AUMA.

Batchwise Vulcanization. Large containers coated with rubber sheets that cannot be placed in autoclaves are subjected to

warm-water vulcanization. The coated containers are filled with water, which is brought to the boiling point by passing steam through it.

However, more often so- called self-vulcanizing compounds are used, particularly for vulcanization in large containers, such as ship containers or wastewater treatment towers. The vulcanization systems of these compounds are adjusted in such a way that they undergo complete vulcanization after processing on the walls of the container at ambient temperature or, after filling, at the temperature of the filling medium. For this process, compounds based on polychloroprene rubber with self-vulcanizing accelerator systems are widely used.

2.5. Extruded Articles [40], [51-55]

2.5.1. *Extruders (see also* ⟶ Plastics, Processing – Extrusion*)*

In the rubber processing industry, extrudates are produced by using *single-screw extruders*. In principle, extruders allow the production of storable intermediate products (pellets, strips), unvulcanized finished products, and further processing to give semifinished products. Special designs are used for the dehydration and drying of rubber after polymerization. An extruder essentially consists of an extrusion die, a screw, a cylinder, machine housing, motor, and feeding device including feed roll, plus heating, cooling, and lubricating systems. Technologically, the *screw and cylinder* form one unit. The screw draws in the compound to be extruded in association with the cylinder, compresses it, conveys it, and shapes it through the die. The thermostatted *feed roll* supports the uniform drawing-in of feed strips or bands. Modern extruders are equipped with measuring devices for bulk pressure and temperature, and with programmable control. This control allows set points to be determined for machine parameters such as the temperature profile of the heating and cooling system or the rate of the take-off conveyor, and possibly the extruder screw as well, and allows them to be compared with the actual value and regulated automatically in some cases. The weight, pressure, and temperature can also be determined by using sensors and displayed graphically.

The size of a rubber extruder is given by the screw diameter *D* (usual diameter 60 – 300 mm standardized) and the screw length *L* (which is identical to the length of the cylinder) as a multiple of the diameter. For example, the usual size of a cold-feed extruder is $L = 16\ D$ (i.e., L: $D = 16$). The extruder is charged either with blank strips or with pellets (see Section Profile Geometry Measurement). There are warm-feed extruders, cold-feed extruders, and cold-feed extruders with homogenizing action.

Warm-Feed Extruders (Fig. 19). The warm-feed extruder is much shorter than the cold-feed extruder. The screw lengths are 4 – 6 *D*. The compression ratio between the volume of the first screw flight in the filling zone and the last screw flight before the extrusion die is 1: 1.1 to 1: 1.4. Single- or double-helix, core- or flight-progressive screws are used. The driving power of such extruders is considerably lower than that of cold-feed extruders with the same screw diameter.

Figure 19. Construction of the warm-feed extruder

a) Extruder head; b) Heating and cooling channels; c) Screw; d) Motor

An open mill is set up before the warm-feed extruder to feed and warm the compound. The compound prewarmed to 85 – 100 °C is fed in strips from the mill into the charge hopper of the extruder. Since the prewarmed compound should be conveyed and compacted uniformly, extruders with short lengths can be used. Warm-feed extruders are used widely in the tire industry and are also used when a high discharge rate is required, e.g., as downstream machines to internal mixers or in combination with cold-feed pin cylinder extruders (duplex extruders) used in the tire industry. In the technical rubber goods industry they have been widely replaced by cold-feed extruders. In the tire industry they are increasingly being replaced by pin cylinder extruders.

Cold-Feed Extruders (Fig. 20). In cold-feed extruders the compound is not preplasticized in feed or prewarming mills. The extruders are considerably longer (screw length 16 – 24 *D*). The necessary plasticization of the rubber compound in the extruder is supported by exact temperature control in the cylinder wall and the screw during extrusion over the entire extruder length. The screws must be self- cleaning.

Figure 20. Cold-feed extruder

a) Vacuum zone; b) Dam

For production of industrial extrudates the cold-feed extruder is equipped with a vacuum pump connected to a vacuum zone in the extruder. The production of pore-free profiles is possible only with this device (vacuum of 0.2 – 0.4 kPA). This additional vacuum zone requires a total screw length of at least 16 *D*. In the vacuum zone the screw is cut deeper or wider, and the flight volumes are increased. While being transported through this zone the compound is decompressed, thus favoring degassing. The so- called dam is situated between the drawing-in and vacuum zones. The compound enters the vacuum zone as a thin film via the dam, so that a sealing effect is achieved at the same time. In the vacuum section the compound head rolls continually between the screw and the cylinder so that new surfaces are constantly being formed, which can be degassed more efficiently. As large a temperature difference as possible (ca. 10 °C) between the screw and the cylinder is also beneficial. Compounds with a high proportion of elastomer, which can be nervy, are more difficult to degas. To bind moisture in the compound and thus make degassing easier, calcium oxide is added. When feeding with raw compound pellets instead of strips, core-progressive screws are used (compression 1: 1.4). For extrusion with strip

feeding, flight-progressive screws are usual.

Cold-Feed Extruder with Homogenizing Action.
Pin Cylinder Extruder (Fig. 21). The cold-feed extruder with homogenizing action has largely replaced warm-feed extruders in the tire industry. The pin cylinder or pin extruder, also known as a cross- current mixing extruder, works on the principle of dividing and diverting the bulk flow.

Figure 21. Principle of construction of pin cylinder extruder

a) Pins; b) Screw

In this type of extruder, pins, which project into the screw flight, are arranged in the cylinder. Through these pins the laminarly rotating rubber compound is divided into partial streams, which are recombined behind the pins. New surfaces are continually created, and intensive heat and oxygen exchange is achieved. The pins act at right angles to the bulk flow — hence, the name of the extruder. By dividing the flow, the formation of a cold core of material that occurs in a feed screw of usual construction is prevented. Mechanical shearing does not occur. Nevertheless, further mixing is achieved by the pin system.

The advantages lie in the considerably higher discharge compared to conventional cold-feed extruders, the smaller increase in bulk temperature, and the lower specific energy consumption. The reason for the higher discharge is the length and width of the flight of the screws used.

Extruders with Shearing Action. Some extruders work on the principle of shearing with flow division and recombination systems [Einwelliger Verteiler Kneter (EVK), Werner & Pfleiderer] or shearing with diversion of the bulk flow (Mailleffer) (⟶ Plastics, Processing). In these special constructions the cold-fed raw compound is plasticized at constant temperature. However, temperature control is extremely difficult, so premature cure onset of the rubber compound often occurs.

Transfer Mix (⟶ Mixing of Highly Viscous Media – Single Screw Mixers). The transfer mix extruder is also equipped with feed flights in the cylinder. The raw compound fed in is sheared and transferred continually from the screw to the cylinder and back to the screw.

Extruders with shearing action are still sometimes used as shaping extruders for internal mixers in mixing lines and as prewarming feed extruders for calenders. They are not important for the production of technical rubber goods.

Shearing Head Extruder (Fig. 22). The shearing head extruder is a machine part equipped with a rotatable core, situated between the extruder and the die. In principle the rubber compound fed in is sheared in a circular gap formed between the rotating core and the cylinder. Through shearing in the circular gap the compound is supplied with a large part of the energy necessary for vulcanization. Vulcanization is then completed in a downstream hot-air channel. The low die swell that can be achieved is an advantage. It results from the cross-linking that begins in the extruder head, the associated dimensional stability of the extruded blanks, and the shorter time and lower energy required for complete vulcanization, compared to hot-air and ultrahigh-frequency (UHF) vulcanization. The downstream hot-air section can be kept relatively short. The system is used for producing extrudates with small dimensions.

2.5.2. *Vulcanization of Extrudates [56-64]*

To start the chemical cross-linking and vulcanization reaction in the blanks after the shaping process, and bring vulcanization to completion in the shortest possible time, an increased amount of energy must be supplied in the form of heat or, in special cases, radiation. Batch or continuous processes can be used. The heat required can be supplied by heat transfer from outside or through dissipative processes within the blank (UHF vulcanization, see Ultrahigh-Frequency Preheating — Hot-Air Vulcanization (UHF Vulcanization)).

The *batch processes* consist of free heating in autoclaves, vulcanization under lead in autoclaves, and autoclave vulcanization of wrapped articles (e.g., rollers). *Continuous processes* are divided into those with or without pressure. *Pressureless processes* include salt bath, hot-air, and fluidized-bed vulcanization, ultrahigh-frequency prewarming with hot-air vulcanization, and irradiation cross-linking processes. *Pressurized processes* include pressurized salt bath, steam tube, and hot-gas vulcanization.

2.5.2.1. *Batch Processes*

Free Heating in Autoclaves. The vulcanization of extruded blanks is carried out in longitudinal vulcanization vessels or in pots. The term *free heating* is derived from the introduction of free-lying blanks, which are stored in pans. Pots are sunk into the floor to make charging easier.

Pressurized vessels can be heated directly by introduction of steam or indirectly by using hot air. However, vulcanization in saturated steam is generally preferred for economic reasons. For hot-air vulcanization the vessel must be equipped with a

circulation ventilator to maintain a uniform temperature over its entire volume. Heating is carried out indirectly via a steam radiator, seldom electrically or with gas. The air in the vessel is pressurized; the pressure can be chosen independently of the vulcanization temperature. To avoid changes in the shape of the blanks before vulcanization, they can be placed in supporting frames of profiles. If they are rolled up in pans, the extrudates are embedded in talc to support them and prevent them from sticking together. Tubing is pulled onto mandrels to avoid deformation. Water-bath vulcanization can also take place in the vessel (production of hard rubber articles). In saturated steam vulcanization, spots of condensed water are formed, which give the vulcanizate an unattractive appearance and can lead to partial undercure on the surface. The condensing of water can be counteracted to some extent by treating the blanks with lubricants before introduction into the vessel. The vulcanization temperature for synthetic rubber is generally 140 – 200 °C; for natural rubber it is 120 – 170 °C because of the danger of reversion.

Vulcanization under Lead. Vulcanization under lead is used for tubing and cables. They are subjected to continuous extrusion coating with lead or batch coated with lead in a lead press. The lead- coated articles are cooled in a water bath, rolled onto large drums, placed in autoclaves, and vulcanized. After cooling, the lead jacket is split and the vulcanized cable or tubing is freed.

To give a uniform thickness of the sheet or coating, the calender rolls can be cambered or crowned (i.e., shaped like a double cone, Fig. 9). The result is that the nip is straight, and the sheet thickness therefore uniform, when the rolls are under pressure. However, the roll geometry is then suitable only for particular operating parameters such as calender speed, sheet thickness, viscosity of the compound, and roll temperature. Fixed crowning severely limits the range of use of a calender and is therefore rarely used.

2.5.2.2. *Pressure-Free Continuous Vulcanization*

The vulcanization section is located after the extruder in the production line. To produce pore-free profiles, vacuum extruders and moisture absorbers in the rubber compound (calcium oxide) must be used.

Hot-Air Vulcanization. Vulcanization of the extrudate takes place in hot-air channels or casing (in the case of coated fabric), whereby the blanks are transported on bands or conveyors. The channels are placed either in a line or more compactly in a three-story construction (length per story ca. 9 – 18 m). Hot air gives poor heat transfer, so relatively high temperatures are necessary, usually 200 – 300 °C. For silicone rubber, temperatures up to 800 °C can be used. Hot-air vulcanization is the oldest continuous process and an important constituent of the production of silicone profiles. Peroxidic cross-linking cannot be carried out by hot-air vulcanization. Such vulcanizates can only be produced continuously in salt baths or steam, as in cable technology. A special type of peroxide (bis-2,4-dichlorobenzoyl peroxide), used in silicone rubber technology, is an exception. This peroxide cross-links at relatively low temperature and can be applied only to the very soft silicone rubber extrudates (there is no heat buildup during extrusion and thus no premature cure onset). The poor heat transfer of hot air is improved considerably by high flow rates. Nitrogen is still used sometimes as a medium, so that peroxidic vulcanization is possible. By using shearing head extruder technology (see Shearing Head Extruder), rapid subsequent complete cure is possible even in relatively short hot-air channels through the homogeneous and intense heating of the entire bulk of the raw compound. The hot-air vulcanization channels can be heated electrically, by IR radiation, with gas, or by a steam-driven heating radiator.

Ultrahigh-Frequency Preheating — Hot-Air Vulcanization (UHF Vulcanization) (Fig. 23). UHF vulcanization is a continuous process in a hot-air channel with dielectric preheating of a polar blank in an electromagnetic alternating field. Machines in Western Europe work at 2450 MHz, in Eastern Europe at 2350 MHz, and in the United Kingdom and the United States at 915 MHz. Adequate preheating of the blank can be achieved only with a high loss factor or loss capacity. The more polar a polymer or compound is, the higher are the energy uptake and the associated loss factor (i.e., the heating effect in the UHF machine). Preheating can occur in hollow conductors or in resonator chamber systems. In the *resonator chamber* the energy fed in is distributed uniformly by reflection off the chamber walls. As a result of the broad energy distribution, large profile cross sections can be vulcanized (e.g., expansion joint bands up to 34 cm long). The *hollow conductor system* gives a very narrow energy distribution. The profile is passed through a stationary electromagnetic wave in the hollow conductor (high energy density, high penetration capacity; profile cross sections up to ca. 5×5 cm can be vulcanized). The hollow conductor system has been almost completely replaced by the resonator system. The resonator chamber (see Fig. 23) allows the use of blades with multiple bores and is more economical. The quantity of compound Q (in kg/h) that can be heated per unit time can be calculated as follows:

$$Q = \frac{P_m \cdot 860\eta}{\Delta T \cdot c}$$

where P_m is the magnetron power (kW); ΔT the temperature rise (°C; temperature of the profile behind the UHF section relative to the extrudate temperature); c the specific heat capacity of the compound (kcal kg^{-1} $°C^{-1}$); η the efficiency of the heating system (dependent on the machine and the polarity of the compound — can be 90 % or more); and 860 is the conversion factor (kcal/h) to kilogram per hour.

Figure 23. Continuous UHF vulcanization

a) Warm air feed; b) Magnetron power: 2.5 kW; c) HF power source; d) Resonator chamber system; e) Extruder

The length of the prewarming section is generally between 4 and 5 m. Hot-air channels, which are completely integrated, have lengths of 6 – 8 m. For UHF preheating, two or four magnetrons are used, for example, usually with a power of 2.5 or 6 kW per magnetron for resonator chambers. The magnetrons can be connected in series, thus adding to the power available. The feeding of electromagnetic energy into the vulcanization chamber is at right angles, either from above or from the side. This arrangement gives an optimally uniform energy field in the cross section. In addition, warm air is passed through the UHF channel in countercurrent, to achieve good and uniform heating throughout the entire chamber

and prevent contamination by condensed plasticizer vapors. This also ensures that the heat content of the compound is not lowered by loss through radiation emission (hot-air temperature ca. 250 °C).

A high efficiency is achieved if as little electromagnetic energy as possible is reflected from the profile thread. The modulation of the microwave position to achieve such a low-reflection adaptation is effected by the introduction of modulation pins into the energy input. In the production of metal-laminated profiles, a radiative energy loss due to the metal band is prevented by the rubber compound extruded onto it.

Fluidized-Bed Vulcanization. In fluidized-bed vulcanization, the extruded compound is passed through a fluidized bed of glass beads heated with an air – steam mixture. The beads adhering to the profile cross section are removed by a stream of air or by brushing. Compared to the salt bath, this process is more suitable for the vulcanization of complicated profile cross sections, but is has been successful to some extent only in the United Kingdom and the United States.

Liquid Curing Medium (LCM) Vulcanization (Fig. 24). Vulcanization takes place in a salt bath directly following the extruder. The extrudate is fed into a molten eutectic salt mixture consisting of 53 % potassium nitrate, 40 % sodium nitrite, and 7 % sodium nitrate. After vulcanization and before unrolling, the salt partially adhering to the vulcanizate surface is removed with brushes in a water bath and reprocessed in special recovery plants to avoid wastewater contamination. Eutectic mixtures of potassium nitrate and lithium nitrate have also been used, which do not contain nitrite and thus do not contribute to the formation of nitrosamines under vulcanization conditions. Compounds with peroxidic cross-linking systems can be vulcanized in the salt melt, in contrast to UHF and hot-air vulcanization. Heat penetration through thick-walled articles is not as good as in UHF vulcanization. Another disadvantage of LCM vulcanization is that the raw profile must be submerged in the salt melt using a steel band to counteract buoyancy. Articles with complex cross sections can be severely distorted. To avoid this, constructional aids are used, e.g., salt spray machines or specially constructed, long run-in sections before the steel band with salt melt sprinkling. Nevertheless, if possible, another vulcanization process should be used for complex articles. The maximum vulcanization temperatures of various types of rubbers in LCM vulcanization are listed in what follows:

NR	up to 210 °C, above reversion
SBR	up to 220 °C
Oil-extended SBR	up to 220 °C, above pore formation
NBR	up to 230 °C
CR	220 – 230 °C
CSM	up to 220 °C, above extensive pore formation
EPDM – sulfur vulcanization	230 – 240 °C
EPDM – peroxide vulcanization	250 °C
CM	≈220 °C
Epichlorohydrin – ethylene oxide terpolymer (ETER)	200 °C

Figure 24. Liquid curing medium (LCM) machine

The use of eutectic metal alloys or organic liquids, such as glycerol, silicone oil, or poly(ethylene glycol), instead of the eutectic salt mixture, has not proved successful.

Radiation Cross-Linking (⟶ Radiation Chemistry). Polymers can be cross-linked through the absorption of radiation. γ-Radiation or β-radiation (electrons) can be used. The energy supplied by such radiation can also lead to depolymerization, as well as cross-linking. Generally, a dose of 50 – 300 Gy (5 – 30 mrd) is applied. Vulcanization systems and cross-linking agents are not necessary; neither is special heat treatment. The elastomer compound can be made up with fillers, plasticizers, and pigments. Activators are sometimes added. Cross-linking follows a radical mechanism. Complex radiation protection measures are required. Another disadvantage is the short penetration depth of β-rays. Also, uniform irradiation of complicated profile geometries is very difficult. On irradiation, ozone, nitrogen pentoxide, and nitrogen monoxide are formed in the airspace. The machines are shielded by concrete walls, whose strength depends on the accelerator voltage. Radionuclides (^{60}Co) can be used as a source of γ- and β-rays. β-Rays are produced mainly by electron accelerators (see also ⟶ Radiation Chemistry; ⟶).

Irradiation cross-linking has been introduced to the cable industry, to some extent into the cross-linking of sheeting (roof sheeting, coated fabric), and to the tire industry to increase the raw toughness of tire parts for further processing by pre-cross-linking with electron rays.

The penetration depth of the electron rays depends on the accelerator voltage and the density of the material. In cable technology, the coating layer thickness to be vulcanized is generally ca. 1 mm (500-kV accelerator).

2.5.2.3. *Continuous Vulcanization under Pressure*

Pressurized Liquid Continuous Vulcanization (PLCV). The PLCV process was developed in the United Kingdom for the vulcanization of cables and reinforced tubing. The molten eutectic salt mixture acting as a heat-transfer agent is passed through a closed system to which the vulcanization trough is connected. The salt melt is pressurized with air or nitrogen. The salt drawn out with the vulcanized cable is fed back into the circulation. A water cooling bath is located downstream of the vulcanization section. Despite some advantages of the system (e.g., production of cross-linked polyethylene with perfect surfaces, higher vulcanization temperatures, higher vulcanization rates compared to steam tube vulcanization, horizontal vulcanization of longer cables), the system has not proved widely successful. The reasons for this are the complex plant construction and the fundamentally difficult handling of molten salt mixtures.

Steam Tube Vulcanization. The continuous process of steam tube vulcanization is used in cable technology. The cable is extrusion coated with rubber compound in an angular extruder head and fed into a steam-filled tube. The tube is flanged directly to the extruder. The steam pressure is ca. 9 – 16 bar, at 180 – 200 °C. The length of the section is generally 50 – 80 m, followed by a cooling water section of 4 – 10 m. The steam chamber is bordered by the angular extruder head on one side and the cooling water section on the other. Cooling water is fed continuously by a high-powered pump. Steam tubes are set up in a rigid horizontal position or freely suspended horizontally (for vulcanization of up to 15-mm cable diameter). Vertically constructed machines are used for vulcanization of heavy duty cable (problem-free guide in high tower plants). Steam tube vulcanization is sometimes also used for the production of armored tubing.

Hot-Gas Vulcanization. Hot-gas vulcanization under pressure in a well-sealed tube is used for the production of hosing and cables. Nitrogen is used as the gas, so that both peroxidic and sulfur cross-linking are possible. An advantage of hot-gas compared to steam tube vulcanization is the fact that pressure and temperature are independent of each other, and the process can run at low pressure but high temperature. Products with a dense, very smooth surface result. In addition, so- called water trees, which can be formed in saturated steam vulcanization of cables by the diffusion of steam into microhollows in the insulation, causing voltage punctures, are not formed here. Since steam also has adverse effects on the steel cord adhesion in hydraulic tubing, the hot-gas technique can be employed to advantage there also.

2.5.3. *Profile Geometry Measurement [54], [65], [66]*

In the continuous production of extrudates the required dimensional tolerance must be adhered to. For complicated profile constructions, monitoring is predominantly carried out destructively in batches, but for simpler profile geometries, continuous, nondestructive testing can be carried out.

The *batch measurement* is still the safest method for establishing the dimensional tolerances of complicated profile cross sections exactly. A thin profile cross section is cut, enlarged, and projected onto a standard drawing by using transmitted light. However, the disadvantage of this process is that faults occurring in continuous production are recognized very late, and articles produced in the meantime must be rejected.

The trend is now increasingly in the direction of *continuous methods of measurement*, which immediately adjust the profile dimension to the given standards by feedback, for example, to the band removal rate. Continuous measuring processes can operate mechanically by scanning rolls, determination of pressure variation by passage through a measuring cell, and determination of weight variations by an inserted band weigher, or optically, by laser technology. Measurement and control by *scanner rolls* are used successfully on rotationally symmetrical profiles, such as cables and hosing. The measurement of *air pressure variations* takes place by passage through a measuring cell, which is heated to a given temperature and has an exactly adjusted internal pressure. A variation in profile thickness is determined from the resulting variation in air pressure. This system is sometimes used for measuring small profile cross sections. Continuous measurement of *weight* to detect variations in profile dimensions is used in the tire industry during tread extrusion. Continuous measurement of the profile geometry by low-powered, *monochromatic lasers* is being increasingly used. Measurement takes place very rapidly without contact. For example, the diameter of round profiles is scanned by high-frequency laser scanners, and a square wave signal is produced at a receiver with the start at t_1 and the end at t_2 (see Fig. 25). The time between t_1 and t_2 corresponds to the diameter of the scanned profile. With the laser scanner method, the profile sag can be measured and controlled immediately on exit from the die before entry into the vulcanization section. To determine complicated profile cross sections the laser head can be rotated around the profile, or two axial measuring heads can be used. The thickness of sheeted or band-shaped profiles can be determined by *laser reflection sensors*. A luminous spot is produced on the profile surface and reflected to the receiving optical instrument. The position of the luminous spot changes when the thickness of the measured object varies. Laser measurement allows the construction of a control system whereby the sensor is set up at the extruder head and usually regulates the take-off conveyor speed. In addition, a second laser measuring head can be connected at the exit of the vulcanization machine.

Figure 25. Determination of profile dimension from the measured signal

2.6. Molded Articles [40], [61], [67-72], [78]

Molded articles are produced by compression, transfer, and injection molding, and in special cases, by embossed molding. The raw compound placed or injected into the mold is vulcanized after the mold has been filled.

2.6.1. *Production Process [67], [73]*

2.6.1.1. *Molding Process*

Compression Molding (Fig. 26). The preformed compound blank is placed in the mold and vulcanized after the press is lowered.

Figure 26. Compression molding process

A) Mold open; B) Mold closed

a) Upper part of mold; b) Flash groove; c) Blank; d) Lower part of mold; e) Heating

Generally, blanks are preformed by a special extruding press so that the same constant blank measurement always results. The blanks can also be preheated (high-frequency preheating 20 – 27 MHz). This preheating guarantees uniform vulcanization and shortened complete cure time. Excess compound (flash) is pressed into the parting lines and flash grooves of the mold. After vulcanization the articles must be deflashed (see Section Deflashing).

Transfer Molding (Fig. 27). The rubber compound is placed in the upper part of the mold. When the mold is closed the compound is pressed through channels into the cavities. Compared to compression molding, higher injection pressures must be used. In addition, more vulcanized waste is produced in this process through the formation of a flat cake in the loading chamber with runners into the injection channels. The blanks must be preformed before being placed in the mold. In transfer molding the rubber compound is plasticized to a certain extent while being injected into the mold cavities. The transfer molding process is useful for the production of complicated small articles. Usually the mold consists of three parts. The middle part can be removed. The upper part is constructed as a piston.

Figure 27. Transfer molding process

a) Piston; b) Compound; c) Middle mold section; d) Lower mold section and caliber; e) Injection nozzle

The *middle part* contains the cylinder, which takes up the rubber compound to be molded, and the injection nozzles. The *lower part* is the actual mold. When the compound is forced through the narrow flow channels, a high heat of friction is produced. This must be considered in compounding since the additional heat can lead to scorching of the compound. Overall, however, a more rapid and homogeneous warming of the total bulk of the blank is achieved compared to compression molding, and vulcanization times can be shortened considerably. Trapped air is pumped out between the parting lines of the mold. Less flash occurs in the parting lines than during compression molding, which also makes degassing considerably easier.

Flashless Process. A modification of the transfer molding process allows the production of molded articles requiring minimum flash. The material is inserted into a cylinder equipped with sealing lips, and pressed through runners to overflow into mold cavities that are mounted floating. One or more runners are assigned and run conically into each cavity. The quantity of raw material must be such that after all cavities have been filled, the formation of a rubber cushion is still possible. This acts as a hydraulic cushion and provides a uniform closing pressure for all cavities. The vulcanizing cushion must subsequently be discarded as waste. When the mold is opened and the cushion is removed, excess material is torn from the molded article at the conical entries to the cavities. The flashless process requires very stable platen presses with well- controlled, plane-parallel heating plates.

Presses. Compression and transfer molding processes are carried out in presses into which the molds are built or inserted. They include all platen presses, the boiler press, and occasionally the articulated lever press.

Platen Press (Fig. 28). Platen presses can be divided into hydraulic column and frame presses, the latter being more recent. Column processes, however, have the advantage of plane-parallel control of the press plates. Platen presses have several heating plates between which the vulcanization molds are inserted. Heating is effected mainly by steam, but also electrically or with oil.

Figure 28. Hydraulic platen press

For the vulcanization of industrial molded articles, the frame press has largely replaced the column press. The number of platens is limited by the manipulation time and the height of the press. To avoid possible heat loss, the vulcanization presses must be jacketed. If the mold is inserted into the platen, the latter is closed with reduced pressure. A surface pressure, normally 35 – 100 bar, is exerted on the mold (high pressure). Such pressures are necessary to achieve uniform pressing of the rubber compound. Articles of large volume must be returned to low pressure (15 – 40 bar) after 10 – 20 min to avoid backrinding (on mold parting lines).

Boiler Press. A vulcanization press with column construction is surrounded by a boiler that can be heated directly. The machine is used if very tall molds need to be heated (e.g., in the production of tall buffers). A range of processes can be found for special applications, such as shoe, conveyor belt, V-belt, and tire presses, as well as jaw-type presses that open on three sides for the production of sheets, mats, or floor coverings.

2.6.1.2. *Injection Molding (see also* ⟶ Plastics, Processing – Injection Molding*)*

The injection molding process is one of the most important processes in rubber technology for producing molded articles. It is suitable both for precision articles and for articles with complicated shapes. The two types of injection molding are screw injection molding and ram injection molding with screw preplasticization. Construction can be horizontal or vertical. With vertical machines, injection can take place from above, below, or the side. With horizontal machines, injection occurs in the direction of the mold. Horizontal systems are predominantly designed as screw injection molding machines, while systems with screw preplasticization and ram injection can be constructed both horizontally and vertically.

Ram Injection Molding Machine with Screw Preplasticization (Fig. 29). The compound has to be redirected on its way from the screw preplasticization into the mold via the injection ram, which is a problem. It contradicts the first-in – first-out principle (i.e., the material that is plasticized first should, for temperature reasons, also be injected first). Specific injection pressures are, for example, between 800 and 1600 bar. Injection volumes of 6400 cm^3 can be realized easily. Construction with *injection from below* (see Fig. 30) is readily accessible. The compound is introduced into the drawing-in shaft via the shortest route. With soft compounds, the fed-in strips are in no danger of tearing.

Figure 29. Ram injection molding with screw preplasticization

a) Plasticizing screw; b) Ram; c) Mold; d) Rubber compound

Figure 30. Types of injection molding machine construction

a) Plasticizing screw; b) Injection; c) Ram; d) Mold

Injection from above is advantageous for fixing metal inserts in the production of rubber – metal articles. The metal inserts are placed at the bottom of the mold and are fixed by the vertical pressure during injection of the rubber compound. *Horizontal construction* is characterized by the short height of the entire machine. In addition, the automatic release in fully automated operations is made considerably easier, as are removal and cleaning of the mold. For the production of rubber – metal articles, it is, however, less suitable. A different machine construction allows injection into different parting lines by using a height-adjustable injection unit (injection from the middle, above, or below). This allows a more flexible construction of the mold since the position of the parting line is not fixed, but can be adjusted to suit the molding (e.g., to give better demolding). Thus, various types of mold can be used in a single molding machine.

The plasticized raw compound charged to the injection cylinder is kept at ca. 80 – 110 °C (max.) to avoid too high a temperature of the reactive compound during its residence time in the injection cylinder. Under all circumstances, the cure onset may begin only when all cavities are definitely filled after the injection process has finished.

Screw Injection Molding Machine (Forcing Screw) (Fig. 31). An axially movable screw acts as the ram and the plasticizing unit. A backflow blocker is built into the head of the screw to hinder backflow during injection. To achieve uniform plasticization over the entire shot volume, the axial shift of the screw should not exceed 4 *D* screw length. The temperature of the compound in front of the screw can be 120 °C; after passage through the nozzle, an increase to 140 °C is possible. This type of machine is preferably of horizontal construction and allows shot volumes of ca. 400 cm^3. The shot volume is limited by the cylinder diameter of the screw. The forced screw process works on the first-in – first-out principle and is also used to operate multistation units arranged on circular tables.

Figure 31. Screw injection molding machine (forcing screw system)

a) Mold; b) Rubber compound; c) Plasticizing screw

A variation is the *screw injection molding machine with storage*. Here, the screw cylinder, not the screw, acts as the ram for injection. For plasticization, the full length of the screw is available over the entire plasticization time. The screw cylinder moves backward or downward with the screw, depending on construction. It is used relatively rarely. These machines are available in horizontal and vertical construction.

In principle, short working cycles can be achieved by using the injection molding process with short vulcanization times, which are very clearly determined by the entry temperature of the raw compound into the mold cavities. The vulcanization systems used must have long flow times and short complete cure times, so that after filling has finished, vulcanization

starts immediately and proceeds completely. The rubber compound is charged as strips or pellets.

The advantages and disadvantages of various injection molding, machines are summarized in Table 1.

Table 1. Advantages and disadvantages of various injection molding machines

Characteristic	Ram injection machine with screw preplasticization (vertical, horizontal)	Screw injection molding machine (forcing screw)	Screw injection molding machine with storage (vertical, horizontal)
Bulk temperature distribution, plasticization	advantage: uniform	disadvantage: nonuniform at axial displacement of the screw >4 *D*	advantage: uniform
Production of articles of large volume	advantage: short screw, short cycle times for large volumes	disadvantage: limited by cylinder diameter	disadvantage: accuracy of dosage difficult to adjust
Fixing of metal inserted part	advantage vertical version: fixing not complicated	disadvantage: fixing difficult	disadvantage: fixing difficult
Rotary bulk article release from mold	disadvantage: only horizontal version can be used, also with automatic release from mold	advantage: automation easily possible, good article release from mold	advantage: automation easily possible, good article release from mold
Corrosion of plasticization screw head	advantage: low danger of corrosion	disadvantage: high danger of corrosion because of additional shear stress (screw injection ram)	advantage: low danger of corrosion because screw cylinder serves as injection ram
Bulk redirection	disadvantage: first in last out	advantage: no bulk redirection, first in first out	advantage: no bulk redirection, first in first out
Compound changing	disadvantage: complex cleaning	advantage: simple cleaning	disadvantage: cleaning relatively difficult, sealing of storage against backflow of material difficult

Machine Control — Process Data Determination [71], [72]. With the aid of sensors built into various operational points of injection molding machines, data can be collected, transmitted, and processed in a computer. Through computerized data collection the evaluation of measured data has become much simpler. Cycles can be compared, and graphical representations displayed immediately making the interpretation of measured data considerably easier. Also, statistical methods of evaluation and documentation of measured values, as demanded by car producers, are possible. In the injection molding machine, important process data such as cylinder temperature, hydraulic pressure, ram distance, bulk temperature, nozzle temperature, mold temperature, inner mold pressure, injection time, subsequent pressure time, dosage time, heating time, and mold opening time can be measured and evaluated by the corresponding built-in sensors. Injection time, subsequent pressure time, dosage time, heating time, and mold opening time are set directly through the machine control. The measured values can be displayed on-line on a screen. Deviations from given tolerances are communicated to the operator by an alarm signal. Upon deviation of actual values from the set point, the mold temperature and heating time are automatically adjusted, whereby the heating time is varied by changing the mold and the bulk temperatures. The injection rate can be controlled by hydraulic pressure.

The heating time determines the progress of the vulcanization, which is given by the stored vulcameter values of the compound. The subsequent pressure, which is an important parameter for the production of articles with minimized flash formation, can also be regulated by adjusting the hydraulic pressure. If strongly undercut articles are produced, trapped air, or burned points as a result of local overheating due to trapped atmospheric oxygen, are a danger. Here, deaeration programs or, preferably, the application of a vacuum (vacuum pressure ca. 5 kPa) can be used to remedy the situation. Evacuation of molds leads to a clear improvement in product quality.

Special Processes. The *injection stamping process* is used for the production of precision articles with extremely low plane-parallel measurement tolerances. In addition, these articles can exhibit only very low flash formation and no formation of knitlines. To carry out the process, a rubber compound, which is predosed exactly, is injected into an injection mold with an opened gap, whose diameter is defined exactly. At the end of the injection process the mold is closed to an equally precisely defined final gap, and the very fine flash formed is cut off (injection – compression process). Exact regulation of the residual gap is very important to maintain the dimensions of the molded articles in the direction of the injection axis. Plane-parallelisms up to ± 0.01 mm can be controlled on the article. To support the plane-parallelism, particularly in multicaliber molds, cold channel molds, which are in themselves more rigid with regard to deformation, are used.

Cold Channel Mold (Fig. 32). In injection molding the vulcanized rubber compound located in the distributor spinner and the feed orifice usually have to be discarded as waste. Particularly in the use of very expensive rubber, this can become extremely uneconomical. The cold channel mold has therefore been developed. The flow channel area is thermostatted with warm water (ca. 90 °C) at a low temperature and well insulated, so that onset of cure of the compound contained in the flow channels is prevented. This part of the compound can thus be reused. Sufficient thermal insulation must be applied particularly between the channel region and the highly heated mold. The injection nozzle cannot have direct contact with the hot mold. The construction requires a great deal of experience and precision.

Figure 32. Cold channel mold

a) Cooled cold channel plate; b) Insulating plate; c) Heating plate; d) Mold

2.6.2. *Mold Cleaning — Contamination [74], [75]*

Contamination of molds represents a serious problem, since it considerably shortens their service life. Contamination can, for example, be caused by high vulcanization temperatures or by the escape of volatile components from the compound, so- called rubber plate-out. Compound residues, which gradually decompose, or residues from mold-release agents with organic components can also be left in the mold. Molds can be cleaned mechanically, physically, chemically, electrochemically, or thermally. Processes are also combined. The different cleaning processes are listed below:

Mechanical	brushing, rubbing, abrasive blasting (lapping), cleaning compounds
Physical	ultrasound
Thermal	fluidized bed, flame treatment, inductive prewarming
Chemical	acid or base treatment
Electrochemical	oxidizing agents, electrophoresis

In the *abrasive blasting process* the mold is cleaned by spraying an aqueous dispersion of abrasive materials (very small glass beads, nutshell chips, sawdust – quartz powder). Abrasive blasting can be combined with a precleaning process in a chromic – sulfuric acid mixture. The latter can also be used alone. Cleaning can be carried out in alkaline baths with and without oil spray support; in solvent baths, or in an alkali bath with ultrasound support (frequency 20 kHz) as well. Molds must be dried sufficiently and protected with washable corrosion protection oil when stored to avoid corrosion or rust.

2.6.3. *Deflashing [75-77]*

A process that allows the production of absolutely flash-free articles is technically possible in principle, but generally not practicable from an economic point of view. The removal of flash, even when the quantity is very small, is therefore necessary and frequently leads to increased rejects because articles can be damaged in the different trimming processes. The flash and burrs can be removed manually by brushes or by cutters or simply by separation at tearing edges that have been provided beforehand. A very important technique is *breaking off the flash in the frozen state* in rotating drums. Freezing is carried out by using dry ice or liquid nitrogen. Temperatures of – 79 °C can be achieved with dry ice, and – 196 °C with liquid nitrogen. Drum trimming is not suitable for articles with internal burrs, but is used frequently for rubber articles with strong walls (trimming by freezing, with steel balls, chains, or beating arms). The investment costs for drum trimming are relatively low. In another technique the article is hit with kinetically accelerated steel or plastic particles (*abrasive blasting*). Abrasive blasting (see Fig. 33) is technically more flexible; the shape of the machine depends on the size of the molded article.

Figure 33. Abrasive blasting process

2.7. Solutions of Rubber Compounds [40], [78]

Solutions of rubber compounds are usually produced in two-shaft trough mixers with a trough that can be heated and cooled. The solid rubber compound previously produced in the internal mixer is charged to the trough mixer together with the solvent and dissolved with the aid of the kneading shaft. The solvent can be gasoline, esters, aromatic hydrocarbons, or a combination of different solvents. A dissolving process in a 70-L trough mixer takes 24 h. The solutions produced are further processed in coating and dough processes or used as adhesive solutions (with a natural rubber base or, for hard rubber modifications, a polychloroprene rubber base). So- called solution dipping for the production of thin-walled articles has been almost completely replaced by corresponding latex technology processes (see Section Dipped Goods).

Coating Processes — Doughs. In the *coating processes,* rubber solution is spread over the impregnated fabric by using special spreading machines with doctor blades, which also regulate the strength of the coating (see Fig. 34).

Figure 34. Spreading machine

a) Machine stand; b) Take-off roll for back cloth; c) Take-up for coated fabric; d) Take-off for uncoated fabric;

e) Spreading roll; f) Spreading knife; g) Hot plate; h) Reversing roll; i) Casing; j) Fabric sheeting

Drying takes place over hot tables or in drying towers. Vulcanization is carried out after the last coating either in hot air, on the rotocure (see Section Vulcanization of Rubber Sheets), or by radiation cross-linking. The solvent can be recovered by a condensation process or by activated charcoal adsorption with subsequent distillation. Awning cloths, cloak and poncho materials, etc., can be rubberized by this process.

In the *dough process*, highly viscous solutions of rubber compounds are applied to very dense textile fabrics. Unlike the coating process, the compounds are applied by a pair of rolls that work at the same velocity, but in opposite direction (coating calender). After application is finished, the fabric is dried. The pretreated fabric is then coated with rubber compound on the calender (e.g., finishing of conveyor belts) (see Fig. 13).

1. Purpose, Scope, and Limitations of Testing

Cross-linked rubber is an important chemical material. Its ease of deformation to a very high extent (e.g., five to ten times the original length), which is almost completely reversible, is its major characteristic. On oscillatory deformation, part of the mechanical energy applied is converted into heat as a result of internal friction. Depending on the composition of the cross-linked rubber, it can act as an effective barrier to gases and liquids, and in extreme cases, it has very low electrical conductivity. Because of these properties it is used in many technical goods, as well as tires.

Testing is performed to determine characteristic properties of the rubber. With the aid of these data the applicability of a rubber for a particular use and its endurance and stability can be evaluated. Properties of the raw rubber and the unvulcanized rubber compound must also be determined to assess processibility (mixing, production of preforms, vulcanization), including changes on long-term storage. The wide variety of uses of rubber means that many properties must be tested. Rubber testing is described in more detail in [1–6].

To some extent, *vulcanized rubber* is difficult to describe in physical terms. Its deformation behavior deviates considerably from the usual Hooke's law for solid materials (deformation proportional to the force, with the modulus of elasticity as the constant of proportionality). Besides elastic deformation, cross-linked rubber also exhibits viscous flow. *Raw rubber and unvulcanized compounds* are also difficult to describe in physical terms. In principle, these are liquids with extraordinarily high viscosity, but the deviations from the usual Newtonian law for liquids (deformation rate proportional to the force with viscosity as the constant of proportionality) are extreme. In addition, these materials exhibit elastic deformation, as well as viscous flow which influences shaping processes. This particular behavior of rubbers depends strongly on time, intensity of stress, and temperature. The result of a test is therefore strongly influenced by these parameters.

Test Standards. Since complete description of the properties of a material by comprehensive testing is normally not possible for economic reasons, test standards have been developed that allow typical properties to be determined reproducibly when certain test parameters are adhered to. Test standards are also the basis of specification agreements in business dealings.

The wide variety of uses of rubber and the particular physical characteristics of raw rub-

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_463

ber, unvulcanized rubber compounds, and vulcanized rubber have led to a large number of test standards. In its "Catalogue 1992" the ISO lists about 320 test standards of the Technical Committee 45 for Rubber and Rubber Products, most of which are specific for certain rubber goods [7]. In the general test standards for solid rubber and its compounds, the ASTM Test Standards Yearbook 1991 includes ca. 85 physical test standards [8]. The German DIN – VDE handbook 47 has about the same number of physical test procedures [9], and the most recent DIN handbook 131 has about 35 standards for chemical test procedures [10].

Each test result can only be assessed if the test standard and all parameters are specified. If there is no national or international test standard, the test must be carried out according to an in-house standard. Only in this way does a comparison with earlier tests become feasible. This applies particularly to tests in the quality control and quality assurance sectors in the production of rubber articles, compounds, polymers, and chemicals. For this area only a limited number of tests are used for permanent control for economic reasons. Their choice is based on experience so that critical deviations can be recognized with certainty. A prerequisite for successful choice is the existence of precise data: long-term repeatability of the test in one laboratory [over weeks to months (some typical values are given in [11])], as well as reproducibility in different testing laboratories. These precision data of a test procedure have been determined systematically for several years and are now included in the test standards. The ASTM standards are particularly far advanced in this regard [8]. A second prerequisite is a knowledge of the sensitivity of the tests, to allow technically relevant material deviations – i.e., differences in test results that are greater than the test precision by a factor of 3 or more [11] – to be recognized with certainty. Further requirements in the important field of quality assurance testing are discussed in [12] and [13].

Tests in the *developmental sector* are generally much more extensive. For development work, sufficiently comprehensive material characterization is necessary to allow prediction of actual technological behavior. The problems that arise can be great (see also Section 2.3.2). This difficulty is clearly indicated with regard to the most important ASTM test standards [14]. For any particular case, sometimes the necessary experience involving the possible use and limitations of selected laboratory test procedures can be obtained only by costly correlation investigations with tests on articles or tires (see [15] for an example concerning abrasion).

However, in this field test precision is not so critical because testing is performed in direct comparison with a standard material. An improvement in a material property can be more easily detected because the improved short-term repeatability of a test can be used to its full advantage.

With laboratory processibility tests of rubber polymers and compounds, analogous problems concerning the accurate prediction of practical behavior can occur [16].

2. Physical and Mechanical Tests

Some review articles supplement the general references cited in Chapter 1 and contain some detailed references [17–20]. Some areas are dealt with comprehensively (e.g., processibility tests [21], performance limits of vulcanized rubber [22], fatigue and fracture [23], viscoelasticity [24], friction [25], and abrasion [26]).

2.1. Test of the Viscoelasticity of Vulcanized and Unvulcanized Materials

(see also → Plastics, Properties and Testing, Chap. 2.1.2., → Plastics, Properties and Testing, Chap. 2.1.3.)

The unique stress – strain behavior of rubber (see Chap. 1) is determined by its molecular structure. Long polymer chains with thermally excited chain segment mobility form loose coils for thermodynamic reasons (entropy maximization). These coils are matted together. If a force is applied, the coil is first slightly deformed, with relatively weak entropy-elastic restoring forces (rubber elasticity); and second, the polymer chains begin to uncoil to achieve maximum entropy again (onset of flow).

The flow processes are severely limited by cross-linking but are still present.

This viscoelastic behavior can be determined by the following tests:

Creep Test. A test specimen is loaded with *constant stress,* and its deformation is determined over a given period of time. The specimen becomes elastically deformed immediately and subsequently flows.

Relaxation Test. A test specimen is subjected to a *constant strain,* and the stress is determined over a period of time. First a stress peak occurs caused by elastic restoring forces. This peak is followed by a decrease in stress (relaxation) because of the onset of flow processes. With unvulcanized material the force ultimately drops to zero. A spectrum of relaxation times (specific to the particular material) characterizes the rate of this relaxation; the spectrum can be determined from the decrease in stress [27]. A reliable test instrument is available [11], [28].

Test Using Periodic, Cyclic Stresses Through Forced Vibrations. A test specimen is subjected to an oscillating sinusoidal deformation and the consequent force variation, which is also sinusoidal, is analyzed [29]. The quotient of force amplitude per cross section of the test specimen and the deformation amplitude is a measure of the dynamic modulus. For rubber this modulus is lower than for metals by a factor of ca. 10 000. In practice, for cross-linked materials the dynamic modulus corresponds to the modulus of elasticity and therefore characterizes the elastic behavior of the material. Because of the flow processes that also occur, the force precedes the deformation [in the region of the deformation maximum, the stress has time to relax to a certain extent (see above)] so that it reaches its maximum earlier to a degree given by the phase angle δ. The phase angle increases with increasing flow; the loss factor $d = \tan\delta$ is a relative measure of the energy loss occurring per cycle, which is converted into heat as a result of internal friction. For vulcanized materials, $\tan\delta$ is typically 0.01 – 0.3; for unvulcanized materials, $\tan\delta$ is > 0.4.

Tests Using Periodic, Cyclic Stresses Through Free Oscillations. Tests can be performed with a torsion pendulum [30]. A rubber band as the test specimen, together with a suspended weight, forms a system that carries out free damped torsional oscillations after impulse. The dynamic modulus of the rubber can be calculated from the frequency of the oscillations. Because of the flow processes occurring in parallel to elastic deformation, mechanical energy is converted into heat and the amplitude of the oscillations continually decreases. The logarithmic decrement $\Lambda = \ln(A_1/A_2)$ (where A_1 and A_2 are the amplitudes of two consecutive oscillations) is a measure of this energy loss and is approximately proportional to the loss factor d.

The last three tests are used both for unvulcanized and vulcanized rubbers. The results obtained in one test can in principle be converted to those obtainable from another test, since they can all be derived from the relaxation time spectrum and a limiting modulus [5]. The spectrum must, however, be determined over a sufficiently long period of time. In practice, because of the experimentally limited range of measuring frequency or observation time, the test temperature is varied greatly, whereby relaxation times can be moved into the measuring range, as given by the Williams – Landel – Ferry (WLF) equation [5].

The derivations mentioned above are, however, only strictly valid in the region of small deformations, as long as there is a linear stress – strain relationship. Stress softening of rubber (Mullins effect [31]) can sometimes be observed in these types of test. Materials containing reinforcing fillers exhibit extreme nonlinearity even at relatively small deformations [32–35].

Low-Temperature Limit of Rubbers. If the test temperature is greatly lowered, the relaxation times of the chain segment mobility are ultimately so long that the polymer chain appears to be immobilized under the stress conditions of the test. The rubber is hard and glassy, and can be deformed only by using correspondingly large forces; it has lost its typical rubber elasticity.

The latter two dynamic tests mentioned, are also used for determination of the low-temperature limit of the rubber [36]. The torsion pendulum [30] has been introduced especially for the determination of the glass transition temperature T_g, i.e., the temperature of the maximum value of the logarithmic decrement. The forced vibration [29] is often used for determination of the technologically relevant low temperature limit T_L for entropy-elastic behavior (e.g., the

temperature at which the dynamic modulus has risen by a factor five times its value at room temperature).

The relaxation time spectrum of raw rubber and rubber compounds is important for processing. Short relaxation times promote filler incorporation and the adhesion of compounds in the molding (building-up) of preforms of rubber articles. Long relaxation times are responsible for the elastic behavior of the compound (e.g., die swell on extrusion and collapse resistance of unvulcanized profiles).

In vulcanized rubber (e.g., in tires), short relaxation times are important for improved adhesion to wet or icy roads, and long relaxation times increase rolling resistance.

Only elongation and shearing of rubber can be achieved by relatively small forces, not compression. This means that in the linear-viscoelastic region and with a Poisson's ratio of $\mu \approx 0.5$, the simplification $E = 3\,G$ (E = modulus of elasticity, G = shear modulus) is valid (i.e., only one modulus value needs to be determined).

2.2. Tests on Unvulcanized Materials

Raw rubber and unvulcanized rubber compounds are characterized principally with regard to their processibility in the fresh state, after storage, and after thermomechanical load.

Besides the tests for linear viscoelastic behavior described in Section 2.1, other tests involve greater loads that are more similar to those experienced in practice. Here, possible changes in the material (e.g., polymer chain scission and possible subsequent reactions) must be determined by rheometric, curemetric, and special tests. Generally, the previous history of the material and the test specimen greatly affect test results and therefore should be defined precisely.

2.2.1. Rheometric Tests

The aim is to characterize the rheological behavior (flow properties) of the material under conditions that are relevant to actual use. Many test procedures are available to shear, compress, or extrude the material [16], [21].

Mooney Shearing Disk Viscometer. The Mooney shearing disk viscometer is the most widely used method [37]. The resistance of the material to prolonged shearing is measured. This resistance is a measure of the viscosity under standardized test conditions. The Mooney viscosity is a very important specification parameter for raw rubber. Problems relating to the precision of the test are discussed in [38–41]. Improvements have been proposed or have already been introduced in more recent standards [41–43], including the pretreatment procedure of the material before the actual test [44].

Extensions of the test using the Mooney viscometer have been described. They involve variations in the shear rate (see, for example, [45]) and measurement of the relaxation (decrease in the torque of the shearing disk after shearing has stopped at the end of the test [46–48]). The former allow determination of the non-Newtonian, i.e., shear-rate dependent viscosity; the latter characterizes the elasticity of simple polymer systems.

Williams and Defo Test and Other Compression Plastometers. By compressing a cylindrical test specimen between two parallel plates, the viscous behavior and subsequent elastic recovery can be determined. The Williams test is standardized [49]. The defo test, preferred in Germany, was standardized [50]; it has gained new importance through modernization and further development to give a very sensitive and meaningful test method [46], [51]. In a special rapid test, only a viscosity-related plasticity number is determined [52] which is used to test the stability of natural rubber to oxidation [53].

Capillary Viscometer. In a high-pressure capillary viscometer the material is extruded through a capillary, whereby extremely high shear rates occur if the material adheres to the capillary wall. This is intended to simulate extrusion and injection molding processes as far as possible. A measure of the viscosity is determined from the pressure and extrusion rate, and characterization of the elasticity from the die swell [54], [55]. A widely used special instrument is described in [56].

Other Tests and Applications. Other rheometric tests are discussed in [21]. Basically all the tests mentioned can be used to assess the storage stability of rubber polymers or compounds by testing before and after storage. For the sake of speed, storage is usually carried out at high temperature (hot air storage). The Mooney viscosity test is used mainly for polymers, and the Mooney scorch test (see below) for compounds.

Material changes resulting from mechanical or thermomechanical load can be determined analogously by testing before and after application of the load [57], [58], or they can be integrated in a test involving strong mechanical loading at elevated temperature [59]. A prolonged Mooney viscosity test can also be used for this purpose.

2.2.2. Curemetric Tests

Curemetric tests are used to characterize the cross-linking reaction in which the rubber compound is vulcanized. The material is sheared weakly through periodic sinusoidal oscillation in a heated chamber, and the resulting stress is measured. The stress increases with increasing cross-linking of the material. The method using a rotor in the chamber [60] leads to delayed heating of the material; the rotor-free test method is more suitable [61], [62].

Analysis of the course of the stress signal with time gives detailed information on material properties relevant to processing, such as the scorch and cure time, the viscosity of the compound, the cross-link density, and sometimes the reversion behavior (decrease in cross-link density after optimum cure). With modern instruments the decrease in the loss factor $d = \tan \delta$ (see Section 2.1) with increased cross-linking can also be determined.

2.2.3. Special Tests

The onset of cross-linking of a compound can still be tested in the Mooney shearing disk viscometer [63]. This Mooney scorch test is also carried out on stored compounds to characterize the scorch behavior and the stability to storage.

A special capillary rheometer, with a ramification flow mold built on, allows simulation of the injection molding process in the laboratory [64], [65]. The mixing process can be simulated and analyzed on a very small scale [66] or on a normal laboratory scale [11], [67]. A special relaxation test is described in [68] and [69].

Tests have been described to assess the tack and green strength of compounds, which are important in compound processing, especially in the building-up of complicated articles such as tires [70–72]; some of these tests have been standardized [73].

For rapid monitoring of the mixing process, the compound density, for example, is determined. For the special monitoring of the filler dispersion achieved in a compound, which is important for rubber properties, a range of tests can be used [74].

2.3. Tests on Vulcanized Materials

Vulcanized rubber needs to be characterized in relation to its performance during a particular use. The properties of the freshly produced rubber and the changes in properties after application of a load are determined, thus simulating a practical situation.

2.3.1. Properties of the Rubber

The linear viscoelastic behavior is tested according to Section 2.1. In addition, many technological tests exist, which are either particularly simple and economical or are based on intended applications.

Hardness. The simplest characterization of elastic deformation behavior is given by the measurement of hardness. The resistance of the rubber to indentation by an object is determined. The Shore A and Shore D hardness are standardized by using a truncated cone and a cone, respectively, as the indenter [75], and the international degree of rubber hardness is determined by using a spherical indenter [76]. Hardness is an important parameter in the specifications for rubber articles. The relation between hardness and modulus is described in [77] and [78]; problems of precision are dealt with in [79].

Rebound Resilience. The standardized test of rebound resilience is the simplest characterization of viscous hysteresis behavior. A metal object rebounds after a free fall from a defined starting position onto rubber [80]. From the height to which it bounces, the percentage of impact energy that is recovered can be calculated. The remainder of the energy is converted irreversibly into heat by rubber hysteresis. Since the hysteresis of rubber depends strongly on frequency, this test, to be regarded as a single-point test in frequency and time, represents only a first rough material characterization. The temperature dependence should also be taken into account.

Tensile Test. The tensile test has great practical importance. A rubber test specimen (dumbbell-shaped rod or ring) is extended in a tensile test machine up to breaking. Typical modulus values (force per cross section) are determined for certain elongations (e.g., 100 %, 300 %) from the forces measured, extensions, and test specimen cross sections, and the limiting values of tensile strength and elongation at break are also determined [81]. Stress softening (Mullins effect [31]) and test specimen preparation (see, for example, [82], [83]) must be taken into account.

Tear Resistance. Mechanically damaged rubber can tear further under relatively low loads. The standardized tear resistance is determined in a tension test by using notched test specimens with different geometries [84]. A critical comparison is given in [85] and a general critical review in [14], which indicates that sufficient experience is still not available to simulate practical conditions with enough certainty in the tests mentioned so far.

Lower Temperature Limit. The lower temperature limit for rubber, which is defined as the transition to the glassy state is important. This limit varies widely depending on the type of rubber and can be affected to a certain extent by compound formulation. Besides the tests described in Section 2.1, tests that are more strongly orientated toward technical applications have been described (brittleness point [86], Gehman test [87]). Other tests are given in [14] and [22].

Other Properties. Tests of the adhesion between rubber and fabric [88] or cord [89], and between rubber and metal [90], and the test for skid resistance [91], are technically relevant. For special applications, the gas or fuel permeability, standardized according to [92] or [93], must be tested.

2.3.2. Endurance and Stability

Changes in properties under load with time are determined. The standardized loads simulate the practical situation. They include static (seals) or dynamic (tires) deformations, contact with aggressive gases or liquids, irradiation and normal aging phenomena, and contact with air or water. Generally in the test standards, only one load at a time is effective. However, this can lead to problems when the results are transferred to practical conditions where the rubber is subjected to several interacting loads in an article (thus shortening its lifetime). The necessary overloading in the laboratory test, in order to obtain any change at all in the relatively short laboratory test times (accelerated process), represents an additional problem. A successful example of testing under accelerating conditions is given in [94]. However, the molecular processes that lead to property changes do not always remain constant on increasing the load (e.g., raising the temperature in an aging test [95]). Carrying out endurance and stability tests and interpreting the results require a great deal of experience (see, for example, [96], [97]). The most important tests are described briefly.

Stress Relaxation. The stress relaxation in constant compression [98] simulates the load on a rubber seal. A less expensive, and therefore often used, test determines the compression set after longer compression of a cylindrical test specimen [99].

Continuous dynamic loads are simulated in flexometer tests [100].

Aging Resistance. The resistance to aging is determined by storage in hot air, air, or oxygen under pressure at elevated temperature and by comparing properties of stored and unstored

test specimens [101]. Generally hardness is determined and the tensile test is carried out; the change in the elongation at break is generally evaluated [15].

The resistance to liquids is characterized by storing test specimens in them and determining changes in weight and volume (swelling) [102]. Comparison tests are possible and generally performed.

Ozone Resistance. Ozone in the air leads to cracks in the surface of deformed rubber. The ozone resistance test simulates this by storing deformed test specimens in air with increased ozone concentration. The test specimen surface is assessed visually for crack formation at defined time intervals [103]. According to ISO, a cyclic deformation of the test specimen is also standardized [104].

Other Tests. In a standardized continuous flexure test, the resistance of the rubber to *crack formation* [105] or *crack growth* [106] is determined. A test of resistance to *cyclic extension* is given in [107].

A rapid laboratory test of *abrasion,* more than 1000 times faster than tire abrasion, should at least make screening tests possible [108]. Laboratory weathering tests are described in [109], and a daylight test is given in [110].

2.4. Physical Material Constants

The physical constants of materials can be determined by the generally valid experimental methods. Thermal expansion, specific heat, thermal conductivity and thermal diffusivity, and density are important.

3. Electrical Tests

Natural rubber and many synthetic rubbers possess very low electrical conductivity and are therefore suitable as electrically insulating materials. By incorporating carbon black, however, the conductivity can be increased by several powers of ten until the antistatic region is reached so that even conducting materials are formed. Rubber compounds can therefore be applied in many different fields.

The test of the *insulating properties* is described in [111], that of *anstistatic* and *electrically conducting rubber* in [112]. Other tests for evaluating electrically insulating materials are standardized [113]. In assessing the results of these tests, it should be taken into account that they are carried out in a standard climate (23 °C, 50 % humidity). The conditions of use of the article can differ considerably from this, with corresponding effects on the electrical properties.

Conductivity measurements are also used to assess the *dispersion of carbon black,* as a simple, rapid monitoring of the mixing process; see [114] for an overview, and [115–120] and [58] for examples. Special conductivity measuring probes in the internal mixer allow, according to [121], incorporation of the carbon black to be monitored during the mixing process [122–127], [11].

With dielectric measurements the course of the cross-linking reaction can be monitored in situ [128], [129].

4. Rubber Analysis [130]

The qualitative and quantitative characterization of polymers, additives, and fillers in a compound generally requires separation into these components and the use of different instrumental techniques. In the past, standardized chemical analysis methods were preferred for determination of the components of rubber compounds and vulcanizates. In [131] the use of the ASTM standard D 297 [132] is described for the reconstruction of vulcanizates. In the following, physical analytical techniques are listed briefly [133], [134] because they require little time for the analysis and give more information on the products investigated. This applies particularly to spectroscopic methods (e.g., solid-state ^{13}C NMR [135], Fourier-transform IR (FT-IR) [136], and pyrolysis mass spectrometry (PY-MS) [137]), which allow a direct analysis of the polymers and other components in carbon-black-filled vulcanizates.

4.1. Compound Formulation

For a quantitative determination of the compounding ingredients in vulcanizates, thermogravimetry is particularly suitable [138]. If the

decomposition regions of the components overlap, as in the case of aromatic oils and polymers [139] or carbonates and carbon blacks [140], the exact proportions of the compounding ingredients cannot be determined. The same applies to polar rubbers, which form carbon black on decomposition under nitrogen [141].

4.2. Polymer Analysis

Identification of the type of polymer in the vulcanizate can be carried out by several methods. In one method, the previously extracted vulcanizate is pyrolyzed [142], e.g., in a high-frequency pyrolyzer, and the gaseous and/or liquid decomposition products are investigated by GC [143], MS [144], or IR [133]. Alternatively, the sample is devulcanized in boiling 1,2-dichlorobenzene [145], and the soluble polymer components are analyzed, e.g., by IR [136]. In the determination of microstructure and the quantitative analysis of polymer blends, solid-state ^{13}C NMR [135] is superior to other analytical methods.

4.3. Filler Analysis

Because of their high IR absorption, inorganic fillers, such as quartz, silicates, or carbonates, can be identified in vulcanizates by FT-IR spectrometry if the technique of attenuated total reflection (ATR) [146] or, in the case of carbonblack-filled vulcanizates, photoacoustic spectroscopy (PAS) [147] is used. Further information, (e.g., on individual filler particles and their distribution) can be obtained by combination of scanning electron microscopy of thin sections of vulcanizates and X-ray microanalysis [138], [148]. The types of carbon black used in the vulcanizate can be determined by using a transmission electron microscope (TEM). Down to the size of HAF blacks, this is also possible with the optical microscope, because of the different coloration of the blacks in the thin section.

4.4. Extract Analysis

Additives such as oils, plasticizers, antidegradants, and accelerators can be extracted from rubber compounds and vulcanizates with methanol or acetone [142]. After evaporation of the solvent, the extract residue is analyzed.

Whereas with spectroscopic methods – apart from mass spectrometry [149] – analysis is often possible only after the components have been separated, with chromatographic methods [150], both qualitative and quantitative determinations can be carried out. HPLC is particularly suitable for the detection of antioxidants, free sulfur, aromatic oils, and accelerators [136] since several samples can be analyzed simultaneously and the individual components can be identified by specific color reactions [151].

4.5. Special Analyses

The identification of exudates on the vulcanizate surface and the cross-link structure in natural rubber vulcanizates cross-linked with sulfur are described in [152] and [153].

1. Introduction

Rubidium [*7440-17-7*] was discovered in 1861 by BUNSEN, who found hitherto unknown spectral lines during experiments on cesium salts obtained from spa water from Bad Dürkheim, Germany. Soon after this, he succeeded in preparing rubidium metal from its tartrate.

2. Properties

Rubidium, the penultimate alkali metal element that is used in industry, is named after two characteristically colored spectral lines (Latin: *rubidus* = dark red). It is a very reactive soft metal with a silvery luster and has the typical chemical properties of an alkali metal. It ignites spontaneously in air and burns with a violet flame. It reacts explosively with water to form colorless rubidium hydroxide [*1310-82-3*], the second strongest base after cesium hydroxide. Rubidium forms four oxides, all of which are colored [1]. Rubidium is monovalent in all its compounds. The isotopic composition of natural rubidium is 72.15 % ^{85}Rb [*13982-12-2*], a stable isotope, and 27.85 % ^{87}Rb [*13982-13-3*], a β^- emitter. Eighteen artificial isotopes are known. Between mass numbers 79 and 84, these are mainly β^+emitters, and between mass numbers 85 and 95 they are exclusively β^-emitters. Some important physical properties of natural elementary rubidium are:

Atomic number	37
Relative atomic mass	85.468
Melting point	39 °C
Boiling point	696 °C
Ionization potential	4.16 eV
Work function	2.19 eV
Normal electrode potential	−2.99 V
Electrical conductivity (at 0 °C)	$8.86 \times 10^4\ \Omega^{-1}\ \mathrm{cm}^{-1}$
Thermal conductivity (liquid)	$29.30\ \mathrm{W\,m^{-1}\,K^{-1}}$
Specific heat capacity	
Solid	$0.332\ \mathrm{J\,g^{-1}\,K^{-1}}$
Liquid (from *mp* to 1093 °C)	$0.368\ \mathrm{J\,g^{-1}\,K^{-1}}$
Gas	$0.242\ \mathrm{J\,g^{-1}\,K^{-1}}$
Heat of fusion	25.71 J/g
Heat of sublimation (at 25 °C)	1004.3 J/g
Heat of vaporization	887.6 J/g
Vapor pressure (427 – 1093 °C)	log (p/mbar) = 7.0493 – 3891.8 K/*T*
Mohs hardness	0.3
Atomic radius	0.243 nm
Covalent radius	0.211 nm
Ionic radius	0.149 nm
Density at 18 °C	1.522 g/cm^3
at *mp*, liquid	1.472 g/cm^3
Crystal structure	Body- centered cubic

3. Raw Materials and Production

[2–6]

Rubidium is very widely distributed and always occurs in combined form owing to its high chemical reactivity. Unlike its homologues lithium and cesium, it is not a major component of any mineral. Nevertheless, it is more abundant in the Earth's crust than lithium and cesium (ca. 120 g/t). Its ionic radius [3] is similar to that of potassium, and it is found in association mainly with this element, but also with the other alkali

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_473

metals. The lithium-containing mica lepidolite [*1317-64-2*] has a high rubidium content (ca. 3 % Rb_2O). Also, pollucite [*1308-53-8*], a cesium aluminum silicate from Bernic Lake in Canada, can contain ca. 1 % Rb_2O.

Due to the similarity in their ionic radii, rubidium is always found in potash salt deposits, e.g., carnallite, sylvite, and langbeinite, which contain 10 – 300 g/t rubidium oxide, Rb_2O [*12509-27-2*].

Rubidium is also widely distributed in very small concentrations in spring water, rivers, lakes, and seas.

Although rubidium is more abundant than lithium and cesium, it is much more difficult to extract than the other alkali metals. Owing to its very widespread distribution and consequent low concentration in ores, rubidium production is nearly always linked to the production of lithium, potassium, and cesium [7]. The process based on the fractional crystallization of carnallite is now only of historical interest. The more selective methods of recovering rubidium from potash salts (in which the quantities of rubidium are large but the concentrations are very low) are based on extraction processes using substituted benzenes as extractants [8–10]. Other techniques include the use of liquid crystals in a d.c. electric field [11], selective cation exchangers based on nitrated and sulfonated polystyrene [12–14], and inorganic cation exchangers consisting of complex salts based on hexacyanoferrates [15], [16]. Acidic MnO_2 can be used in an adsorption – elution cycle to concentrate rubidium [17]. The liquid waste from the production of cesium from pollucite can also be treated to give rubidium (see → Cesium and Cesium Compounds, Chap. 3.).

Rubidium is obtained from the mixed alkali metal carbonates that are a byproduct of the abandoned production of lithium from lepidolite in the United States. After precipitating the less soluble dicesium hexachlorostannate, the rubidium is precipitated as dirubidium hexachlorostannate [*17362-92-4*]. It is converted to rubidium chloride [*7791-11-9*] by pyrolysis. Rubidium carbonate [*584-09-8*] is obtained by precipitating dirubidium zinc hexacyanoferrate(II) [*128804-74-0*] followed by thermal oxidation. In all processes, the main difficulty is separating the rubidium from the potassium and cesium.

In more recently published research work, the following processes are described: the extraction from weathered rocks by sodium chloride solution in a high-frequency electrical field or with dipicrylamine and ultrasound [18], and the thermal decomposition of rubidium alum (rubidium aluminum sulfate [*7488-54-2*]) in the presence of calcium oxide followed by dissolution to form rubidium sulfate [*7488-54-2*] [19]. Another proposal is the recovery of rubidium from intermediates that arise in the production of aluminum oxide from bauxites and nephelines by means of solvent extraction with long-chain *p*-alkylphenols [20].

4. Rubidium Compounds

Important compounds of rubidium are:

- Rubidium hydroxide, RbOH [*1310-82-3*], M_r: 102.48, *mp*: 301 °C, solubility in water: 180 g/100 mL at 15 °C
- Rubidium carbonate, Rb_2CO_3 [*584-09-8*], M_r: 230.95, *mp*: 837 °C, solubility in water: 450 g/100 mL at 20 °C
- Rubidium hydrogencarbonate, $RbHCO_3$ [*19088-74-5*], M_r: 146.49, *mp*: 175 °C (decomp.), solubility in water: 54 g/100 mL at 20 °C
- Rubidium fluoride, RbF [*13446-74-7*], M_r: 104.47, *mp*: 775 °C, *bp*: 1410 °C, solubility in water: 130.6 g/100 mL at 20 °C
- Rubidium chloride, RbCl [*7791-11-9*], M_r: 120.92, *mp*: 715 °C, *bp*: 1390 °C, solubility in water: 77 g/100 mL at 0 °C
- Rubidium bromide, RbBr [*7789-39-1*], M_r: 165.38, *mp*: 682 °C, *bp*: 1340 °C, solubility in water: 98 g/100 mL at 5 °C
- Rubidium iodide, RbI [*7790-29-6*], M_r: 212.37, *mp*: 642 °C, *bp*: 1300 °C, solubility in water: 152 g/100 mL at 17 °C
- Rubidium nitrate, $RbNO_3$ [*13126-12-0*], M_r: 147.47, *mp*: 310 °C, *bp*: ca. 1700 °C, solubility in water: 44 g/100 mL at 16 °C, solubility in water: 42 g/100 mL at 10 °C

These inorganic compounds are colorless or white, and have the properties typical of salts of alkali metals. They are mostly prepared by wet chemical reactions.

5. Quality Specifications and Analysis

Rubidium salts are marketed with purities up to > 99.5 %. Rubidium metal is obtainable with purities of 99.5 % and 99.8 % [2].

Metallic impurities are usually determined by atomic absorption spectroscopy, and more recently with ICP (inductively coupled plasma) excitation. The elements are then detected by conventional optical detectors or by mass spectroscopy (ICP-MS). The homologous elements sodium, potassium, and cesium can be analyzed by emission spectroscopy. The analysis of rubidium metal must be preceded by reaction to give an aqueous salt solution. Anions can be determined photometrically (e.g., sulfate, phosphate) or argentometrically (chloride).

6. Storage and Transportation

Because rubidium metal is very reactive toward water, steam, ice, air, and many other gases and substances, special precautions are necessary. The metal is shipped in sealed evacuated glass ampoules, or is hermetically sealed in metal containers packed in vermiculite and enclosed in a second outer metal container. Due to its low melting point (*mp* 39 °C), melting cannot be prevented during transportation to or through hot climatic zones. Rubidium salts are hygroscopic and must be protected from moisture during storage and transport. Radioactive rubidium preparations are subject to special storage and transport regulations.

7. Uses and Economic Aspects

Uses. Rubidium compounds are used in psychiatry and medicine [21], in magneto-optic modulators [22], solid-state lasers [23], phosphors (rubidium aluminate) [24], Rb – C molecular sieves for hydrogen absorption [25], paper pigments [26], glass hardening by ion exchange [27], components of electrolytes for fuel cells [28], in Na – Rb zeolites for separating mixtures of hydrocarbons [29], and for density gradient centrifugation. In the early investigations of the Fischer – Tropsch synthesis, RbOH was used to activate the iron catalyst [30]. Owing to its high ionic conductivity silver rubidium iodide, $RbAg_4I_5$, is of interest as a solid electrolyte for primary and secondary cells [31] and as an electrographic picture recording material [32].

The use of rubidium compounds to activate catalysts of various types may increase in terms of quantity. However, potassium and cesium often compete with rubidium in this application. Three types of catalyst may be distinguished. The most important group includes rubidium-activated transition metal oxide catalysts for the production of organic chemicals, e.g., the oxidation of acrolein to acrylic acid [33] or of C_4 hydrocarbons to maleic anhydride [34], the ammoxidation of isobutene to methacrylonitrile [35], or the oxidation of *o*-xylene or naphthalene to phthalic anhydride [36]. The second category includes the activation of metallic catalysts, e.g., silver contact catalysts for ethylene oxide manufacture [37]. The third category comprises rubidium compounds that themselves have catalytic properties, e.g., Rb_2O used in polyester production by polycondensation [38] and in NH_3 synthesis [39], and RbOH for the dehydrocyclization of 1-hexene to form benzene [40].

Economic Aspects. Rubidium manufacturers do not publish production or sales figures. World consumption in 1979 was estimated to be ca. 2 t [2], and has increased slightly since then. The demand for the metal is small compared to the demand for its compounds. In 1996, the price of 99.5 % pure metal was 0.70 – 1.00 $/g, and for 99.8 % pure metal, 0.80 – 6.00 $/g [2]. Prices for rubidium compounds (99.5 %) are in the range 250 – 550 $/kg, and for > 99.5 % pure compounds, 550 – 750 $/kg [2].

8. Toxicology and Occupational Health

It is not possible to give a precise assessment from the small amount of available data on the toxicity of rubidium. In plasma and blood, the properties of rubidium are not dissimilar to those of potassium, as far as can be determined from physiological investigations. The hazard potential is therefore regarded as low [41].

Rubidium metal is designated as a“flammable solid” and “dangerous when wet”, and

should be handled with great care under a protective gas or inert solvent.

In its compounds, the precautions and protective measures to be taken are determined by the anion. Thus, RbOH is very caustic, RbF shows the toxicity typical of the alkali metal fluorides, and $RbClO_4$ [*13510-42-4*] and $RbNO_3$ are oxidizing agents.

1. Introduction

Salicylic acid [*69-72-7*], also called 2-hydroxybenzoic acid or *o*-hydroxybenzoic acid, is widely distributed in the plant kingdom in the form of esters.

Some 2400 years ago Hippocrates prescribed decoctions of willow leaves as a treatment for fever and pain. The active principle in willow leaves is salicylic acid, whose biosynthesis is based on the deamination of phenylalanine to *trans*- cinnamic acid which, when hydrolyzed and oxidized at the β- carbon atom, gives salicylic acid.

Salicylate esters are found in several plant genera, the principal ones being *Salix*, *Spiraea*, and *Gaultheria*. For example, methyl salicylate is present in large quantity in the form of a glucoside in birch bark, various spiraeas (meadowsweet or *Spiraea ulmaria*), and wintergreen leaves.

Salicylic acid was first obtained in 1838 by R. Piria, an Italian chemist at the Institute of Pisa, by melting salicylaldehyde, obtained from meadowsweet, with caustic potash. In 1844 the French chemist Cahours obtained salicylic acid by hydrolysis of methyl salicylate. The final step, namely preparation from a natural source, was accomplished in 1874 by the German chemist H. Kolbe, who synthesized the acid by carboxylation of sodium phenoxide, a process still in use.

Salicylic acid and its derivatives are used mainly to synthesize pharmaceutical products and as intermediates in the production of dyes and agrochemical and perfumery products.

2. Physical and Chemical Properties

Physical Properties. Salicylic acid, $C_7H_6O_3$, M_r 138.12, crystallizes in the form of colorless needles (water) or monoclinic prisms (ethanol), *mp* 159 °C; salicylic acid begins to sublime at 76 °C; flash point (closed cup) 157 °C; heat of sublimation 81.8 kJ/mol; density d_4^{20} 1.443; dissociation constants K_1 1.05×10^{-3}, K_2 4.0×10^{-14} (19 °C); vapor pressure 1.66 mbar (110 °C) and 19.3 mbar (150 °C); solubility (per 100 g of solution) in methanol 38.46 g (21 °C), ethanol 34.87 g (21 °C), chloroform 1.55 g (30 °C), benzene 1.00 g (30 °C); solubility (per 100 mL of solution) in diethyl ether 23.4 g (17 °C), acetone 31.3 g (23 °C); extremely soluble in ammonia, insoluble in liquid sulfur dioxide. Solubility in water:

°C	0	10	20	40	60	80
g/L	0.8	1.2	1.8	3.7	8.2	20.5

Salicylic acid is an aromatic *o*-hydroxy carboxylic acid, and in contrast to its *meta* and *para* isomers (→ Hydroxycarboxylic Acids, Aromatic, Chap. 4.1.) it is subject to intramolecular hydrogen bonding and steam volatility. It also sublimes more readily than its isomers (→ Sublimation, Chap. 4.2.1.), and is substantially more acidic: dissociation constants for the *meta* and *para* isomers are 8.7×10^{-5} and 3.3×10^{-5}, respectively.

Chemical Properties. The difunctional salicylic acid molecule combines the properties of phenols with those of aromatic carboxylic acids. One equivalent of alkali hydroxide neutralizes only the carboxyl group. An excess of hydroxide is required to form the dialkali salt, from which the free OH group reforms in the presence of carbon dioxide. Chelation occurs with some metal ions such as Fe(III), leading to a violet coloration. Salicylic acid can be used as an indicator in EDTA determinations of Fe(III) [6].

Salicylic acid is esterified by alcohols in the presence of strong acids without significant etherification. Combined ether – esters can be prepared from dialkali salicylate in the presence of alkyl halide; these are converted by alkaline hydrolysis into the corresponding alkoxybenzoic acids. The phenolic OH group is etherified by an alkaline aqueous solution of dialkyl sulfate, and esterified by the action of acyl halides or acid anhydrides. Reduction with sodium and amyl alcohol affords tetrahydrosalicylic acid, whose oxidation product is pimelic acid [7]. Catalytic hydrogenation of salicylic acid esters over Raney nickel produces esters of *cis-trans*-2-hydroxycyclohexane carboxylic acid [8].

Since electrophilic reactants attack the less sterically hindered 5-position in preference to the 3-position, it is possible to obtain either 5-substituted or 3,5-disubstituted derivatives directly. For example, the monosubstituted products obtained on nitration, sulfonation, halogenation, alkylation, acylation, or coupling with diazonium salts are generally salicylic acids substituted at the 5-position. Derivatives substituted exclusively at the 3-position are obtained by indirect means, such as substitution of sulfosalicylic acid at the 5-position, followed by elimination of the sulfonic group. More severe conditions may lead to decarboxylation as well. Thus, 2,4,6-trinitrophenol (picric acid) is obtained upon treatment of salicylic acid with fuming nitric acid, and tribromophenol results from treatment with bromine in the presence of water.

When heated at or above its melting point salicylic acid decomposes into phenol and carbon dioxide. Under a carbon dioxide atmosphere at 230 °C the main product is phenyl salicylate. At 250 °C, xanthone is formed in parallel with phenol. For the behavior of salicylic acid as a function of temperature see [9].

Xanthone

Analysis. Quantitative determination of salicylic acid is generally accomplished by titration in an alkaline medium. Kolthoff's method permits salicylic acid also to be determined with a bromide solution, which converts it to tribromophenol [10]. For trace analysis it is convenient to use colorimetric methods with the reagent iron(III) chloride [11]. Thin-layer chromatography (TLC) provides a convenient test of purity, since each of the isomeric acids can be detected by alkaline coupling (caustic soda) with diazotized *p*-nitroaniline, spraying with Fe(III) chloride, or fluorescence under UV light. The TLC approach is often replaced today by reversed-phase high-performance liquid chromatography (HPLC).

3. Production

Kolbe – Schmitt Synthesis. Salicylic acid is prepared on an industrial scale by the Kolbe – Schmitt synthesis from dry sodium phenoxide in a stream of carbon dioxide at 150 – 160 °C and a pressure of 5 bar.

The use of pressure (Schmitt, 1884) results in a yield of about 90 %, whereas without pressure (Kolbe, 1874) the yield does not exceed

50 % because disodium salicylate and phenol are formed in equivalent amounts.

Alternative reaction mechanisms for the carboxylation of phenoxide salts have been described in the literature [12]. 4-Hydroxyisophthalic acid, which yields salicylate by direct release of CO_2 (or by carboxylation of phenolate), has been discussed as a possible intermediate in the reaction process [13]. An electrophilic substitution mechanism via a complex formed between phenol, one molecule of CO_2, and an alkali metal, has also been suggested [14]. Temperature, the nature of the alkali metal, and the CO_2 pressure are all of decisive importance with respect to the reactivity and selectivity of the phenoxide [12, 15].

The various stages in the industrial synthesis of salicylic acid [16] are outlined in Figure 1. Carboxylation may be carried out if in autoclaves heated with steam or heat-exchange fluids and equipped with counterblades, or in powerful mill autoclaves. The process is still conducted mainly in a batchwise manner. To ensure that reaction proceeds satisfactorily, the reaction mass must not only be in a finely ground state during the carboxylation stage, but water must also be rigorously excluded. The presence of water reduces the yield by protonating the phenoxide and releasing alkali-metal hydroxide, which then converts CO_2 into carbonate with the regeneration of water. Water may also be formed in situ via a secondary etherification reaction [15]. Sodium phenoxide is prepared with a 1 – 2 % molar excess of caustic soda; larger amounts of alkali lead to the formation of water, as described above. Anhydrous sodium phenoxide may be prepared either in the autoclave mixer itself by evaporation of an aqueous solution of phenoxide, starting at normal pressure and then gradually introducing vacuum, or in special drying equipment. In order to prevent discoloration and tar formation it is important that the carbon dioxide contains as little oxygen as possible (< 0.1 %).

The carboxylation step is exothermic: $\Delta H = -90.1$ kJ/mol. Using a 6 m^3 reactor, about 3 t of sodium phenoxide is converted into salicylic acid in 25 h. Phenol derived from the formation of disodium salicylate is recovered by distillation. The crude sodium salicylate is dissolved in a mixture of water and a decolorizing agent (e.g., activated charcoal, aluminum, or zinc powder [17]). Salicylic acid is then precipitated with sulfuric acid. This synthesis can be accomplished in a continuous manner by working with a solution of the anhydrous phenoxide in a suitable medium. Recommended solvents are phenol itself [18], higher alcohols [19], dialkyl ketones [20], nitrobenzene [21] and, as a dispersant [22], gasoline.

Other Processes. Consideration has been given to producing salicylic acid by air oxidation of *o*- cresolate at 230 °C in the presence of a copper-based catalyst [23] or copper benzoate (175 – 215 °C) [24]. Alkaline copper benzoate can also be converted by heat treatment into salicylate directly [25]. Benzoylsalicylic acid is an intermediate in the synthesis of phenol from toluene by the Dow process (→ Phenol, Chap. 4.2.).

Salicylic acid can also be obtained by fermentation of such polycyclic aromatic compounds as naphthalene with the aid of microorganisms [26] (→ Biotechnology).

4. Quality Specifications, Storage and Transportation, and Environmental Protection

Quality Control. Technical-grade salicylic acid obtained from the Kolbe – Schmitt process is already extremely pure: salicylic acid content 99.5 %; phenol, *p*-hydroxybenzoic acid, or 4-hydroxyisophthalic acid 0.05 – 0.1 % (as impurity); ash < 0.1 %; water 0.2 %.

An even higher quality acid (pharmaceutical grade) can be obtained by crystallizing the sodium salicylate from water at a temperature not exceeding 20 °C [27], or by sublimation of the acid at 20 mbar and a temperature of 154 °C

Figure 1. Simplified representation of salicylic acid production by the Kolbe – Schmitt method

[28] or with the aid of a carrier gas. A more modern process achieves sublimation directly by utilizing the heat of neutralization from the reaction of sodium salicylate with hydrogen chloride [29].

The quality specifications of the European Pharmacopoeia are limted to the following items: identity check; color (ethanolic solution); melting point (158 – 161 °C); assay (99.0 – 100.5 %); if sulfated ash (< 0.1 %); heavy metals (< 20 ppm); chloride (< 100 ppm); if sulfates (< 200 ppm); and loss on drying < 0.5 %.

Storage and Handling. Salicylic acid dust is combustible in air. The low combustion energy for the process indicates a high level of combustion sensitivity, so appropriate measures must be adopted to avoid sources of ignition and to protect against potentially severe explosive effects. Explosive conditions can be avoided by maintaining the oxygen level at < 8 %.

The explosive characteristics of salicylic acid dust (particle size < 100 µm) are as follows: minimum combustion temperature, 490 °C; minimum combustion concentration, 30 g/m^3; minimum combustion energy, < 5 mJ; maximum pressure produced, 7.2 bar; maximum rate of pressure increase, 216 bar/s [unpublished work carried out by Rhône-Poulenc in accordance with ISO 6184/1].

Transportation. Salicylic acid is not subject to any transport restrictions. The acid is transported in bags (25 kg), drums (50 kg), big bags (500 – 1000 kg), or bulk containers (15 – 20 t).

Environmental Protection. Effluent and gaseous emission problems are comparable to those posed by phenol.

Freshwater ecotoxicity of salicylic acid on *Daphnia magna*: (ED_{50} 24 h; immobilization): 180 mg/L (AFNOR T 90 301 Standard, French). Salicylic acid is readily biodegradable and very slightly bioaccumulable.

5. Uses and Economic Aspects

Salicylic acid is used mainly in the synthesis of acetylsalicylic acid, the most commonly dispensed pharmaceutical product. In the form of esters, amides, and salicylic acid salts it serves as a starting material for other pharmaceutical products. Technical-grade salicylic acid is used primarily as an intermediate in the production of agrochemical products, dyes, and colorants, as well as in the rubber industry and in the manufacture of phenolic resins.

Salicylic acid itself offers therapeutic benefits in the treatment of rheumatic disorders, for which purpose it is usually administered in the form of the readily soluble sodium salt. On account of its keratolytic action the acid is also widely used for cleaning the skin and removing scales.

By virtue of its bacteriostatic properties it is used as a disinfectant or preserative; however, its presence is not permitted in foods.

Economic Importance. The distribution of salicylic acid in terms of application can be estimated as follows: acetylsalicylic acid 55 %, esters and salts 18 %, resins 10 %, dyes and colorants 10 %. The development and introduction of new analgesics that compete aggressively with acetylsalicylic acid has had a direct effect on market evolution, and a steady decline in the consumption of acetylsalicylic acid has been observed. It is expected that the discovery of new uses will stabilize the situation.

6. Salicylic Acid Derivatives

Salts. The carboxyl group in salicylic acid is easily converted into salts by the action of metal carbonates. In order to prevent discoloration, aqueous salt solutions should be kept slightly acidic. Salts are obtained in solid form by concentrating their aqueous solutions.

Sodium salicylate [*54-21-7*], $C_7H_5NaO_3$, M_r 160.11, forms white, odorless, shiny crystalline flakes; solubility (in a solution of 100 mL): water 125 g (25 °C), ethanol 17 g (15 °C). The technical-grade product (99.5 %) is obtained by evaporating a solution of sodium salicylate; pharmaceutical-quality material [30] is prepared by two successive crystallizations of sodium salicylate hexahydrate from a 45 % aqueous solution at 10 °C. Sodium salicylate is used as an analgesic, antipyretic, and antineuralgic.

Other Salts. Besides sodium salicylate, a number of other common salts are known (e.g., ammonium, magnesium, calcium, aluminum), as is morpholine salicylate. Several of the salts are marketed under various trade names.

Esters. Several important salicylate esters are described below (→ Flavors and Fragrances, Chap. 2.6.5.). These are formed by reaction with the appropriate alcohols. All are soluble in both ether and alcohol, but only sparingly soluble in water.

Methyl salicylate [*119-36-8*], oil of wintergreen, $C_8H_8O_3$, M_r 152.15, is a colorless, oily liquid with a characteristic odor, *mp* − 9 °C, *bp* 222 °C, d_4^{20} 1.184. Methyl salicylate is synthesized by heating a mixture of salicylic acid and methyl alcohol in the presence of sulfuric acid. It is used to treat neuralgia and rheumatism, as well as to stimulate capillary blood circulation. It is also used as an insecticide, sunscreen, fragrance, and synthetic intermediate.

Benzyl salicylate [*118-58-1*], $C_{14}H_{12}O_3$, $M_r = 228.25$, is a clear liquid or colorless to opaque crystalline mass with a characteristic odor, *mp* 24 °C, *bp* 318 °C, d_4^{15} 1.180. It is obtained from a mixture of sodium salicylate and benzyl chloride, or by transesterification of methyl salicylate in the presence of benzyl alcohol. It is present in ylang-ylang and carnation oils, and is widely employed as an additive in soaps, in detergents, and in perfumery products (→ Benzyl Alcohol, Chap. 8.4.).

Isoamyl salicylate [*87-20-7*], $C_{12}H_{16}O_3$, M_r 208.26, is a colorless liquid with the fragrance of orchids, *bp* 270 °C, d_4^{20} 1.050. Isoamyl salicylate is used as a fragrance and stabilizer in perfumery and as an antirheumatic agent (topical application).

Phenyl salicylate [*118-55-8*], salol, $C_{13}H_{10}O_3$, M_r 241.22, is a colorless, crystalline powder, *mp* 43 °C, *bp* 172 °C at 16 mbar. It is obtained from a mixture of salicylic acid and phenol in the presence of sulfuric acid, or by transesterification of methyl salicylate in the presence of sodium phenoxide. Phenyl salicylate is used as an antiseptic, preservative, as a sunscreen and a general photoprotective agent for synthetic products, and as an emollient.

Acetylsalicylic Acid (→ Analgesics and Antipyretics, Chap. 2.1.,; → Anti-inflammatory – Antirheumatic Drugs, Chap. 3.1.; → Cardiovascular Drugs, Chap. 5.3.1.1.). Acetylsalicylic acid [*50-78-2*], $C_9H_8O_4$, M_r 180.15, is isolated as monoclinic colorless needles or crystalline powder (from water), or as flat platelets (from isoamyl alcohol), *mp* 143 – 144 °C depending on the heating rate and crystalline form; dissociation constant $K = 2.8 \times 10^{-4}$ (25 °C); solubility (in 100 mL of solvent): water 0.25 g (15 °C), ethanol 20 g (25 °C), ether 5 g (18 °C). The compound hydrolyzes to some extent during recrystallization from water.

Acetylsalicylic acid is prepared by reacting acetic anhydride with salicylic acid at a temperature of < 90 °C either in a solvent (e.g., acetic acid or aromatic, acyclic, or chlorinated hydrocarbons) or by the addition of catalysts such as

acids or tertiary amines [31]; for quality specifications see [30]. Acetylsalicylic acid is used as an antipyretic, analgesic, and anti-inflammatory agent, and it has an antirheumatic effect. Acetylsalicylic acid also has antithrombosis and anticoagulant properties. It is marketed by Bayer as a consumer product under the trade name Aspirin and as a bulk product by Rhône-Poulenc (Rhodine).

Other Derivatives.

Salicylamide [*65-45-2*], $C_7H_7NO_2$, M_r 137.13, is a white crystalline powder, *mp* 140 °C, sparingly soluble in water and soluble in alcohol. It is obtained by the ammonolysis of methyl salicylate [32]. Salicylamide is used as an analgesic, antipyretic, antirheumatic, sedative, and fungicide.

Salicylanilide [*87-17-2*], $C_{13}H_{11}NO_2$, M_r 213.33, forms colorless and odorless crystals, *mp* 136 – 137 °C. It is sparingly soluble in water and soluble in alcohol and chloroform. The substance is prepared from a mixture of salicylic acid and aniline in the presence of PCl_3 [33]. Salicylanilide and particularly its derivatives are powerful fungicides, and are used in the synthesis of dyes, colorants, lacquers, and textiles, and also as a disinfectant. It is distributed commercially under the trade name Shirlan (ICI).

3-Chlorosalicylic acid [*1829-32-9*], 3-chloro-2-hydroxybenzoic acid, $C_7H_5ClO_3$, M_r 172.57, *mp* 180 °C, is obtained either by the carboxylation of sodium 2-chlorophenoxide (Kolbe – Schmitt synthesis) or by chlorination of 5-sulfosalicylic acid, followed by displacement of the sulfonic group by means of superheated steam [34].

4-Chlorosalicylic acid [*5106-98-9*], 4-chloro-2-hydroxybenzoic acid, $C_7H_5ClO_3$, M_r 172.57, *mp* 211 °C, is prepared from 4-aminosalicylic acid by the Sandmeyer process [35] and used as a synthetic intermediate. The *N*-butylamide derivative of 4-chlorosalicylic acid (Jadit, Hoechst) is an antimycotic.

5-Chlorosalicylic acid [*321-14-2*], 5-chloro-2-hydroxybenzoic acid, $C_7H_5ClO_3$, M_r 172.57, *mp* 176 °C, is synthesized either by the chlorination of salicylic acid or by the Kolbe – Schmitt method starting from sodium 4-chlorophenoxide and CO_2 at 150 °C (higher temperature should be avoided since the decomposition reaction may be explosive) [34, 36]. It is used as an intermediate in the synthesis of agrochemical products and disinfectants. The ethanolamine salt of 5-chlorosalicylic acid 4-nitro-2-chloroanilide (Bayluscid, Bayer) is used as an antiparasitic agent to combat schistosomiasis (→ Molluscicides).

Bayluscid

5-(2,4-Difluorophenyl)salicylic acid [*22494-42-4*] (Diflunisal, Merck), $C_{13}H_8F_2O_3$, M_r 250.20, *mp* 212 – 213 °C.

Diflunisal

This compound can be prepared by acetylation of 2,4-difluorobiphenyl, followed by oxidation to 4-acetyloxy-2′,4′-difluorobiphenyl which, when heated under pressure in the presence of potassium carbonate and carbon dioxide, undergoes hydrolysis and carboxylation [37]. Diflunisal is a newly marketed analgesic [38] (→ Analgesics and Antipyretics, Chap. 2.1.; → Antiinflammatory – Antirheumatic Drugs, Chap. 3.1.).

7. Toxicology

Salicylic acid and its derivatives are resorbed by the skin and mucous membranes. Salicylic acid esters dissociate hydrolytically under the influence of esterases. Depending on the pH of the urine, salicylic acid is either oxidized to gentisic acid, or it is eliminated by the kidneys in the form of salicyluretic acid or glucuronide salicylate. Since the elimination rate of salicylic acid is lower than the rate of resorption, in certain cases there is a danger that it may accumulate in the body.

Salicylic acid has keratolytic activity and is a tissue irritant. In the stomach this irritant action affects mainly the mucous-producing cells and striated cells. Long-term treatment with

salicylates slows the rate of blood coagulation by reducing platelet aggregation. Prostaglandin biosynthesis is also inhibited by salicylic acid and its derivatives, which partly explains their anti-inflammatory action. The acid and its derivatives display antipyretic and analgesic effects, and are fungicides and bacteriostatic agents [39].

Symptoms of cutaneous and pulmonary hypersensitivity to salicylates are well known, but it appears that these reactions are not always the result of true allergy. A decrease in the synthesis of prostaglandins and, consequently, other biologically active mediators is evidently involved here as well. Cross-sensitization has been established, for example, between methyl salicylate and acetylsalicylic acid [40–42].

One-time doses in excess of 10 g may prove fatal. The main cause of such *acute* intoxication is the disturbance of the acid – base equilibrium. Severe cases of intoxication may produce delirium, tremor, respiratory insufficiency, sweating, exsiccosis, hyperthermia, or coma. Symptoms of less severe intoxication include hyperventilation, tinnitus, nausea, vomiting, impaired vision and hearing, vertigo, and nervous disorders.

In the case of *chronic* intoxication, symptoms include digestive disorders and gastric and intestinal pain, sometimes with serious hemorrhaging, which nevertheless often remains hidden. Salicylate-induced anaemia, which may be observed in cases of chronic administriation, is an iron deficiency due to hidden bleeding. In the elderly the symptoms of chronic intoxication are often of a neuropsychiatric nature, including confusion and agitation. Despite the very harmful effects of salicylates on tissues, no hepatic or renal problems have been reported to date following chronic administration of pure forms of the compound [34, 43–45].

Experiments with various species of animals have shown that administration of relatively large doses of salicylic acid and its derivatives may have a teratogenic effect. The causative agent is probably salicylic acid. These findings have never been confirmed in humans, however, and there are no grounds for concern assuming the maintenance of appropriate hygiene and proper working conditions [46–49]. In addition to possible local symptoms of irritation due to salicylic acid and its derivatives, the major safety consideration is a risk of allergy. All renewed contact with these products should be avoided by those with a previous history of hyperallergic reactions.

1. Introduction

Saponins are glycosides (see → Carbohydrates) occurring primarily in plants but also in starfish (*Asteroidea*) and sea cucumbers (*Holothuridea*). Properties generally considered to be shared by this group of natural products are surfactant activity, hemolytic action, steroid- complexing ability, and biocidal capability.

The characteristic soapy lather formed when saponin- containing plant extracts are agitated in water provides this group of secondary metabolites with its common name (Latin *sapo* = soap), although this property is shared with structurally related compounds (→ Cardiac Glycosides). Other properties are characteristic of particular types of saponins rather than all members of the class.

Saponins are categorized according to the structure of the aglycone moiety (*sapogenin*) and the number of linked sugar chains. Aglycones can be divided into triterpenoid and steroid sapogenins. Steroid saponins with basic properties are termed glycoalkaloids.

Hexoses common in all saponins are β-D-glucose (glc), β-D-galactose (gal), and α-L-rhamnose (rha); pentoses are α-L-arabinose (ara) and β-D-xylose (xyl). Pentoses occur primarily as pyranosides, less frequently as furanosides (f).

Saponins linked to one or two sugar chains are called *monodesmosides* and *bisdesmosides*, respectively (Greek *desmos* = chain). Trisdesmosidic saponins are rare [1,2]. Mild hydrolysis of saponins yields *prosapogenins*, neutral glycosides with less than three sugar units, or acidic or basic glycosides with one sugar unit. Prosapogenins are less soluble than saponins and do not have typical saponin properties.

1.1. General Properties

Surfactant Activity. The well-known ability of saponins to cause frothing has long been used to detect these materials in plants or plant extracts. The combination of a hydrophobic aglycone and hydrophilic substituents accounts for the amphiphilic nature of saponins. Increased length and branching of the sugar chain correlate with enhanced surfactant power. Hence, triterpenoidal bisdesmosides are more active in this sense than monodesmosides [3].

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_485

Hemolytic Activity. Saponins vary considerably in their ability to lyse erythrocytes. Different glycosides of the same sapogenin differ in activity as a function of the type and structure of substituents [4,5]. Bisdesmosides are generally less potent than monodesmosides. Introducing polar hydroxyl groups into the aglycone decreases activity, whereas esterification restores it. The linkage position of the sugar chain in triterpenoids also influences reactivity; thus, C-3 glycosides are more reactive than saponins with a C-28 glycosidic substituent.

Steroid-Complexing Ability. Saponins form insoluble complexes with cholesterol [6] and other sterols. This affinity is more pronounced with steroid saponins and glycoalkaloids than with triterpenoids.

Biocidal Activity. Monodesmosidic saponins exhibit fungitoxic or fungistatic and weak antimicrobial activity [7]. Examples include the specific action of α-tomatine [8] and the oat (*Avena sativa*) root saponin avenacin [9]. Steroid saponins and glycoalkaloids generally demonstrate more pronounced action, whereas triterpenes exhibit a broader spectrum of effectiveness.

The permeabilization of crucial cell membranes probably explains the toxicity of saponins to mollusks [10] and other invertebrates [11]. Ecdysterone-like activity [12] and the repellent or antifeedant action of saponins against termites [13], leaf- cutting ants [14], and the potato beetle [15] have been reported. Aquatic vertebrates such as fish and tadpoles are affected through permeabilization of their gills [16], resulting in a rapid loss of physiological function.

1.2. Distribution

Saponins occur mainly in plants of the subdivision *Angiospermae* of the division *Spermatophytae*. Steroid saponins are restricted mostly to the class *Monocotyledoneae*, a known exception being the saponins of foxglove (*Digitalis* sp.). Triterpene and glycoalkaloid saponins are found primarily in plants of the class *Dicotyledoneae*, a more recently discovered exception being saponins isolated from montbretia (*Crocosmia crocosmiiflora*) [17]. Certain families of the class *Dicotyledoneae* (e.g., *Solanaceae, Hippocastanaceae, Primulaceae, Rosaceae,* and *Caryophyllaceae*) are especially rich in saponin- containing genera.

Monodesmosides are concentrated in the outer tissues of seeds, roots, and bark, consistent with their function as a barrier against microorganisms, whereas bisdesmosides are more abundant in leaves and stems. Secretion of proteolytic enzymes by fungal hyphae triggers conversion of the more soluble (and, therefore, transportable) bisdesmosides by specific glycosidases [18] into the more active monodesmosidic saponins.

Animal saponins are restricted to representatives of the phylum *Echinodermata*. Species of the class Holothuridea (sea cucumbers) contain triterpene saponins, whereas saponins from species of the class *Asteroidea* (starfish) contain steroids. These saponins induce avoidance responses in susceptible predator species [19].

1.3. Isolation

Methods for saponin isolation and purification are covered in several reviews [20–22]. Ground dried or fresh specimens are extracted after optional defatting with solvents such as methanol, ethanol, their aqueous mixtures, or, in the case of glycoalkaloids, slightly acidified water. Formation of artifacts due to enzymatic or solvolytic cleavage of glycosidic bonds or acid- catalyzed elimination and rearrangement of the aglycone must be prevented by suitable choice of conditions.

Distribution of a crude extract between water and butanol separates the saponins from such water-soluble compounds as oligosaccharides. Precipitation with organic solvents (e.g., ether or acetone) or complexing agents (e.g., cholesterol) permits further concentration.

Saponins with free carboxylic acid groups can be purified by ion-exchange chromatography. For cases in which further enrichment by crystallization is not possible, chromatographic techniques are used for the separation of crude saponin mixtures. Methods such as high-performance thin-layer chromatography (HPTLC), high-performance liquid chromatography (HPLC), and droplet countercurrent

chromatography (DCCC) [23] have gained wide acceptance. Methods have been reported for isolating saponins from roots of ginseng (*Panax schinseng*) [24] and *Bupleurum falcatum* [25] by preparative HPLC of crude extracts.

1.4. Structure Elucidation

Historically, saponin structures were deduced after methylation and acid hydrolysis to aglycones and partially methylated sugars. However, this method leads to artifacts, so milder hydrolysis methods have been developed. Relatively large amounts of purified material are still needed for classical structural analysis.

The advent of modern spectroscopic methods has simplified the task. Fast-atom bombardment mass spectrometry (FAB – MS) facilitates the sequencing of sugar chains, while ^{1}H and ^{13}C NMR [27] techniques are used to establish specific linkages and resolve ambiguities. Structures of saponins from the starfish *Asterias forbesii* [28], *Astragalus ernestii* [29], and *Allium giganteum* [30] were elucidated by modern two-dimensional NMR methods.

1.5. Analysis

Analytical procedures must be adapted to the particular application in question. Crude estimates of saponin content are obtained via gravimetric methods [31]. Most technical-grade saponins are mixtures rather than single substances. Quantitative estimation of their makeup is accomplished by measuring the surface tension of solutions, their foaming power, and their hemolytic activity [32].

Saponins or saponin mixtures for pharmaceutical applications require analytical methods more specific to particular active compounds, such as spectrophotometric quantitation of a saponin color reaction [33, 34]. Combinations of methods including thin-layer chromatography – densitometry (TLC – DM) [35], gas chromatography – mass spectrometry (GC – MS) [36], LC – MS [37], HPLC [38], and radioimmunoassay (RIA) [39], have been reported for ginseng saponins and other compounds.

2. Pharmacology

Toxicology. In contrast to poikilothermic animals, saponin toxicity to homeothermic species by oral intake is quite low (50 – 100 mg/kg). The significance of saponins as components of the human diet or of animal feeds has been reviewed extensively [20]. Saponins exhibit different spectra of toxicity on parenteral or intravenous application (LD_{50} 0.7 – 50 mg/kg). The hemolytic action of many saponins prevents their intravenous administration, although detoxification by complex formation with serum cholesterol, albumin, or other plasma constituents reduces this effect.

Membranolytic saponins combine irreversibly with cell membrane systems and produce lesions [40] with a pore diameter of about 8 nm. Various structural models for the complex have been proposed [40, 41]. The role of cholesterol as the primary binding site for saponins in cell membranes has been challenged [42], and various saponins have been shown to interact in different ways with erythrocytes and liposomal membranes with respect to cholesterol, phosphatidylcholine, and distearoyllecithin [43]. The theory that β-glucosidase-induced hydrolysis of the glycosidic bond is an essential step in membranolysis [4] cannot explain changes induced by saponins in the osmotic behavior of liposomes devoid of β-glucosidase [44]. A unifying theory of saponin action on membranes has still to be developed.

Pharmacology. Claims of therapeutic activity for saponins are numerous, with the result that saponins have been denounced by some as panaceas [45].

Resorption of saponins by the small intestine is generally low [46], but enzymatic or bacterial decomposition in the large intestine [47] has been demonstrated. Permeabilization of cells of the small intestinal mucosa [48] reduces their capacity to transport nutrients and increases secretion. A therapeutic benefit is increased secretion in the nasal pharyngeal cavity after administration of cough syrup containing extracts of roots from *Primula officinalis*, *Glycyrrhiza glabra,* and *Gala senega*.

Anti-inflammatory activity has been reported for saponins from the seed of the horse chestnut (*Aesculus hippocastanum*) [49] and *Panax*

inseng (Greek *pan* = all, *axos* = cure) [50,51]. In the former case, pharmacological action was blocked by adrenalectomy, hypophysectomy, or sympatholytic drugs. Antiexudative and antigranulomatous action was explained in terms of activation of corticosterone secretion.

The saponin from *Glycyrrhiza glabra* and the hemisuccinate of the corresponding aglycone (carbenoxolone) are used to treat gastric ulcers [52]. Chemical modifications of the aglycone have been reported to reduce side effects [53]. The ammonium salt of the aglycone is used as an antiallergic agent, and the same effect is reported for saponins from *Ilex crenata* [54].

Hypocholesterolemic effects of saponins might be due to a reduction in the uptake of dietary cholesterol by complex formation, increasing bile salt excretion, or direct interaction with sterols in the membranes of mucosal cells [20]. Active saponins have been found in soybean (*Glycine max*) [55] and *Quillaja saponaria* [56].

Psychotropic effects are reported for ginseng saponins [57], and patents have been filed for analgesic, sedative, and cardiovascular-activating effects [58] as well as antitumor activity [59].

Antiviral activity of saponins has been reported against the herpes- and poliovirus [60], Epstein – Barr virus [61], and human immunodeficiency virus (HIV-1) [62].

Bisdesmosidic saponins solubilize monodesmosides [63], an adjuvant effect that seems to increase immune response to vaccines [64] and the uptake of β-lactam antibiotics [65] after oral administration.

3. Plant Saponins

3.1. Steroid Saponins

Aglycones of monodesmosidic steroid saponins from plants consist of a hexacyclic spirostanol system, whereas bisdesmosides are derived from the pentacyclic furostanol system or a hexacyclic structure such as that in nuatigenin. Hydrolysis of C-26 glycosidic linkages of furostanol sapogenins results in cyclization to spirostanols. Therefore, furostanol saponins carry the designation "proto-" prefixed to the name of the corresponding spirostanol saponin. Especially in the older literature, the suffix "-oside" provides another indication of a furostanol saponin. Nuatigenin saponins rearrange to the spirostanol derivative isonuatigenin on acid hydrolysis [66].

Aglycones are named after the plant sources from which they were first isolated. C-25 (*S*)-epimers of known C-25 (*R*)-sapogenins are assigned the prefix "neo-", whereas C-25 (*R*)-epimers of known C-25 (*S*)-sapogenins are given the prefix "iso-". Epimers with a C-3 α-OH instead of a C-3 β-OH are designated by the prefix "epi-".

Monodesmosides have linear or branched sugar chains linked in most cases to the C-3 β-OH group, whereas furostanol bisdesmosides display an additional glycosidic linkage at C-26. Besides the common sugars listed previously, less prevalent sugars include D-fucose (fuc), β-D-2′-deoxyribose (drib), and β-D-apiose [api(f)]. For a review of steroid saponins, see [67].

Spirostanol Saponins. Figure 1 provides the structures for a number of spirostanol aglycones. Most spirostanol saponins are monodesmosides with a single glycosidic bond at the C-3 β-OH. This is also true of hydroxylated sapogenins such as digitogenin (**15**) and paniculogenin (**14**). Monodesmosidic steroid saponins exhibit typical saponin properties, such as strong hemolytic activity.

Important saponins derived from diosgenin (**1**; $\rightarrow$ Hormones) and its C-25 (*S*)-epimer yamogenin (**2**) are dioscin [rha1 $\rightarrow$ 2(rha1 $\rightarrow$ 4glc)-**1**] (see Fig. 2 for an example of the signifance of the abbreviated notation used here and elsewhere) and gracillin [rha1 $\rightarrow$ 2(glc1 $\rightarrow$3glc)-**1**], two glycosides first isolated from wild yam (*Dioscorea* sp.). Dioscin has been reported in a number of plant sources, including palms [68]. The aglycones are important sources for steroid synthesis, as are hecogenin (**12**), smilagenin (**16**), and its epimer sarsasapogenin (**17**). The latter were first isolated from *Agave* sp. and *Smilax crenata*, respectively. Sarsasapogenin (**17**) yields the monodesmoside parillin, glc1 $\rightarrow$ 2[rha1 $\rightarrow$ 4 (glc1 $\rightarrow$ 6glc)]-**17**, and the bisdesmoside sarsaparilloside (**18**).

Figure 2. Alternative notational schemes for saponins, using dioscin as an example

A number of steroid saponins have been isolated from foxglove (*Digitalis purpurea, D. lanata*), of which digitonin, glc1 → 3gal1 → 2 (xyl1 → 3glc)1 → 4gal-**15**, and its aglycone digitogenin (**15**) are the most important. Digitonin forms very insoluble complexes with cholesterol, and has been used as a reagent for the determination of this sterol. Minor sapogenins in *Digitalis* sp. are gitogenin (**13**), tigogenin (**8**), and its epimer neotigogenin (**9**). The saponin glc1 → 3glc-**13** was isolated from Agave cantala [69].

Together with diosgenin (**1**) derivatives, the pennogenin (**3**) saponin dioscinin, rha1 → 4rha1 → 4(rha1 → 2glc)-**3** was isolated from the palm *Trachycarpus wagnerianus* [70]. Another saponin was isolated from *Dracaena mannii* [71] and characterized as rha1 → 2rha1 → 3glc-**3**, showing antimicrobial activity.

Saponins of ruscogenin (**4**) were isolated from *Ophiopogon* sp. [72] and identified as ophiopogonin B (rha1 → 2fuc-1-O-**4**) and D [rha1 → 2(xyl1 → 3fuc)-1-*O*-**4**]. In both cases the sugar chain is attached to the C-1-hydroxyl group.

Chlorogenin (**10**) was first isolated from *Chlorogalum pomeridianum*. Its saponins were used historically as a poison to stun fish, while at the same time leaving them edible by humans.

Furostanol Saponins. As already mentioned, furostanol saponins are readily converted to spirostanol saponins by dilute acid or β-glucosidases.

Leaves and stems often yield the protosaponins of spirostanols isolated from other parts of the plant.

The hydroxyl group at C-22 can be displaced by alkyl alcohols to yield alkylprotosaponins [73], or eliminated with acetic acid. The resulting $\Delta^{20,22}$-furostene saponins are termed pseudoprotosaponins. The isolation of furostene bisdesmosides [69] represents the first report of a genuine pseudoprotosaponin in nature.

Furostanols are easily distinguished from spirostanol saponins with Ehrlich's reagent [74], and also by IR spectroscopy, since furostanols lack the characteristic absorption bands of a C-22 spiroketal moiety.

The best known example of a bisdesmosidic steroid saponin is sarsaparilloside (**18**) (R = glc1 → 2[rha1 → 4(glc1 → 6glc)] –) from sarsaparilla, the dried root of *Smilax aristolochiaefolia*, used as a flavoring in beverages.

Furostanol glycosides isolated from garlic (*Allium sativum*) [75] were shown to be derived from chlorogenin (**10**). Mild hydrolysis yields antifungal spirostanol saponins.

Furostanols of tigogenin (**8**) were isolated from *Nicotiana tabacum* [76], of sarsasapogenin (**17**) from *Asparagus sp.* [77], of diosgenin (**1**) from *Balanites aegyptiaca* [78], and of gitogenin (**13**) from *Trigonella foenum-graecum* [79]. Trisdesmosidic furostanol glycosides have been reported for ruscogenin (**4**) saponins [72].

Avenacosides A and B were isolated from oat seeds [80] and identified as glc1 → 2(rha1 → 4glc)- and glc1 → 3glc1 → 2(rha1 → 4glc)-glycosides of nuatigenin-26-glucopyranoside (**19**), respectively. A highly specific β-glucosidase (avenacosidase) [81] yields the antifungal 26-desglucoavenacosides. Nuatigenin saponins from *Solanum aculeatissimum* have recently been proposed as a starting material for steroid synthesis [82].

Nuatigenin-26-glucoside (**19**)

Other Steroid Systems. Saponins from *Polypodium vulgare* are derived from a rare type of cholestanone system with a hydroxytetrahydropyran ring at C-17 [83].

Uses. Spirostanol and furostanol saponins of diosgenin (**1**) and its epimer yamogenin (**2**) were the first natural starting materials for the industrial synthesis of pregnenolone and progesterone (→ Hormones, Chap. 3.2.). Hecogenin (**12**), smilagenin (**16**), and sarsasapogenin (**17**) are also used as educts for steroid hormones. However, the growth in demand could not be satisfied by saponins alone, so the microbiological conversion of sterols such as stigmasterol to steroid precursors and total synthesis have both become important alternatives.

3.2. Glycoalkaloids (→ Alkaloids)

Glycoalkaloids are limited principally to the genera *Solanum, Lycopersicum, Cestrum*, and *Veratrum* of the family Solanaceae. They share a common C_{27} cholestane structure but differ in the structures of their side chains. Because of the presence of these materials in cultivated plants [84, 85], the corresponding structures have been known for some time.

Nitrogen analogues of the spirostanol steroid saponins, with nitrogen replacing an oxygen in the spiroketal ring, are called spirosolanes. Depending on the stereochemistry at C-22 they belong to either the solasodane (22*R*) or the tomatidane (22*S*) group. Analogues in which the 3-β-hydroxyl group has been replaced by an amino group are called aminospirostanes.

Solanidanes and *solanocapsines* have contiguous six-ring systems, whereas epinitrilocholestanes have a tetrahydropyridine ring bound to C-20 of a cholestane structure. Glycosides of the spirosolane and solanidane types are bound exclusively through the C-3 β-OH group.

The spirosolane-type aglycone solasodine (**20**) and its saponin α-solamargine (rha1 → 2 (rha1 → 4glc)-**20**) are analogues of diosgenin (**1**) and dioscin, respectively. Soladulcidine (**21**) and 15-hydroxysoladulcidine (**22**) correspond to tigogenin (**8**) and chlorogenin (**10**), respectively (cf. Fig. 3).

Sapogenin	CAS registry no.	Δ	C-5 H	R

Hydroxysoladulcidine (**22**)	[*4912-43-0*]		α	OH

Figure 3. Solasodane-type glycoalkaloids

Solasodine (**20**) can be converted by *N*-acetylation and subsequent rearrangement to a $\Delta^{20,22}$-furostene, useful as a precursor in steroid synthesis [86]. This reaction is also feasible with the C-22 epimers tomatidine (**23**) and tomatidenol (**24**). Saponins such as α-tomatine (gal1 → 2(xyl1 → 3glc)1 → 4gal-**23**) can be used as natural sources for steroid precursors. The distribution of α-tomatine and its significance have been reviewed [87].

Tomatidine (**23**) [*77-59-8*]
Δ^5, tomatidenol (**24**) [*546-40-7*]

The glycoalkaloid solanine was found in the cultivated potato (*Solanum tuberosum*) and identified as consisting of saponins derived from solanidine (**25**), namely, α-chaconine (rha1 → 2(rha1 → 4glc)-**25**) and α-solanine (rha1 → 2(glc1 → 3gal)-**25**) [88]. Other sapogenins found in *Solanum* sp. (see

Fig. 4) are leptinidine (**26**) [89] and demissidine (**27**), with the saponins demissine (glc1 → 2(xyl1 → 3glc)1 → 4gal-**27**) and commersonine [glc1 → 2(glc1 → 3glc)1 → 4gal-**27**].Chemical degradation of solanidanes to steroids has not been achieved [90].

Figure 4. Solanidane-type glycoalkaloids

Solanocapsine (**28**) has been isolated as a sapogenin from *S. pseudicapsicum* [91]; no glycoside has yet been reported.

Solanocapsine (**28**) [*639-86-1*]

Natural epinitrilocholestanes (Fig. 5) include verazine (**29**) and tomatillidine (**30**). Intermediates in the conversion of spirosolanes to steroids [92] and in the transformation of spirosolanes to solanidanes [93] have similar structures.

The aminospirostanes jurubidine (**31**) and paniculidine (**32**) from *S. paniculatum* [94] are sapogenins of furostane glycosides such as jurubine (**33**).

Uses. The spirosolanes solasodine (**20**), tomatidine (**23**), and tomatidenol (**24**) serve as natural sources for steroid synthesis. The use of enzymes [95] for glycolysis of solasodine saponins produced by plant cell cultures has been proposed [96].

R = H, jurubidine (**31**) [*6084-44-2*]
R = OH, paniculidine (**32**) [*138464-37-6*]

3.3. Triterpene Saponins

Triterpene glycosides are the most common saponins in nature, and they have been reviewed extensively [20–22]. A derivative of triterpenoids was found in tertiary sediments [97].

Monodesmosides have linear or branched sugar chains, usually linked to the C-3 β-OH group. The common sugars listed previously are supplemented by such less frequently encountered sugars as β-D-fucose (fuc), β-D-fructose [fru(f)], β-D-quinovose (qui), β-D-glucuronic acid (glcA), and β-D-galacturonic acid (galA).

Oleananes. Saponins derived from β-amyrin (**34**) are the most common triterpene glycosides (cf. Fig. 6).

Figure 6. Oleanane-type sapogenins

The variability of substituents is immense. The most frequently hydroxylated carbon centers of the ring system are C-2, C-16, C-21, and C-22. Saponins of hydroxylated aglycones are esterified with organic acids (e.g., acetic, butyric, 2-methylbutyric, tiglic, angelic, and benzoic acids). One example is the principal saponin glc1 → 2(glc1 → 4glcA)-**47** of horse chestnut, which is esterified at C-22 with acetic acid and at C-21 with tiglic or angelic acid. The complete mixture of saponins is called escin.

Of the methyl substituents, C-23, C-24, C-28, C-29, and C-30 are most frequently oxidized to hydroxymethyl, aldehyde, and carboxylic acid groups. Sapogenins with a C-28 carboxylic acid function are present in plant leaves and stems in the form of bisdesmosides with an acyl – glycosidic linkage to a second sugar chain. Enzymatic cleavage of the acyl – glycosidic bond yields the biologically more active monodesmosides. One example is found in a report on the isolation of two oleanolic acid (**54**) saponins from *Momordica cochinchinensis* [98], momordins Id [xyl1 → 2 (xyl1 → 3glcA)-3-*O*-**54**] and IId [xyl1 → 2(xyl1 → 3glcA)-3-*O*-**54**-28-*O*-glc]. Quinoside A from *Chenopodium quinoa* has been reported [2] to be a trisdesmoside of hederagenin (**59**), 3,23-bis (glc)-**59**-28-*O*-ara3 ← 1glc.

Saponins from licorice, the extract of *Glycyrrhiza glabra*, have a keto group at C-11. The resulting enone structure facilitates UV detection during HPLC separation. The composition, uses, and analysis of licorice have been reviewed [99]. The main sapogenin from this source is glycyrrhetic acid (**38**), with the principal saponin being glycyrrhizin (glcA1 → 2glcA-38).

A subgroup of the oleanane-type saponins consists of glycosides with an ether bridge between C-13 and C-18 referred to as epoxyoleanane saponins (Fig. 7).

Examples are protoprimulagenin A (**70**), found in *Primula* sp., cyclamiretin A (**72**) and its saponin cyclamin [xyl1 → 2(glc1 → 3glc)-1 → 4(glc1 → 2-ara)-**72**] from *Cyclamen europeaum*, and the saikogenins (**75**) – (**77**) from *Bupleurum falcatum*, used in traditional oriental medicine [100].

Epoxyoleanane-type saponins are very sensitive to extraction conditions, and they yield artifacts upon acidic cleavage of the ether linkage. Protoprimulagenin A (**70**) yields primulagenin A (**48**), whereas saikogenins (**75**) – (**77**) rearrange to $\Delta^{11,13(18)}$-dienes not found in natural sources.

Ursanes. Aglycones of the ursane type (cf. Fig. 8) are derived from α-amyrin (**78**). Reports describe the isolation of saponins of ursolic acid (**79**) from both maté (*Ilex paraguayensis*) [101] and *Cynara cardunculus* [102]. Ilexgenin A (**82**) was first isolated from *I. pubenscens* [103]. An example of acyl – glycosidic linkages in ursane-type saponins is the asiaticoside rha1 → 4-glc1 → 6glc-28-O-**84**.

Dammaranes. In addition to saponins derived from oleanolic acid (**54**), the roots of *Panax schinseng* contain saponins originating from the tetracyclic dammarane-type aglycones (see Fig. 9). Elucidation of their true structures was complicated by rapid epimerization at C-20 during isolation. Progress in the identification of saponins from *Panax* sp. has been reviewed [104].

Ginsenosides of protopanaxadiol (**87**) are bisdesmosides with glycosidic linkages at C-3 and C-20, whereas protopanaxatriol (**88**) has glycosides linked to C-6 and C-20. Major saponins are ginsenosides Rb1 (glc1 → 2glc-3-O-87-20-O-glc6 ← 1glc) and Rg1 (glc-3-*O*-**88**-20-*O*-glc).

Lupanes and Hopanes. Sapogenins of the pentacyclic lupane and hopane systems are not very common compared to other triterpenes. Although unsubstituted ring systems are present in fruit waxes and other nonpolar plant materials, saponins are scarce. A saponin from *Asparagus gonocladus* has been isolated and identified as the glc1 → 2rha-glycoside of betulinic acid (90) [105]. Known hopane-type sapogenins include **91** and **92**.

Uses. Commercial applications of triterpene saponins are based largely on their surfactant properties and their ability to form oil-in-water emulsions. Formerly used as emulsifiers in X-ray film manufacture (→ Disperse Systems and Dispersions, Chap. 5.3.7.) and as components of detergents or cosmetics, saponins have been largely replaced in these applications by synthetic compounds.

Figure 9. Dammarane-type sapogenins

The extract of *Glycyrrhiza glabra* containing glycyrrhetic acid (**38**) and glycyrrhetin is used by the tobacco and food industries for flavoring purposes [99]. As already mentioned, this sapogenins and saponins also have pharmaceutical value for the treatment of ulcers and gastritis [52]. Saponins used as expectorants are isolated from *G. glabra*, *Gala senega, Primula officinalis,* and *Hedera helix* [106].

A vast number of folk medicines contain saponins, and they are used as tonics and stimulants. The best-known examples are ex-

tracts of *Panax schinseng,* containing ginsenosid saponins, and *Bupleurum falcatum*, containing saikosaponins, which are important in traditional oriental medicine.

R = CH_3, lupeol (**89**) [*545-47-1*]

$\Delta^{15,17(21)}$, R = OH, R^1 = H, mollugogenol B (**91**) [*22554-64-9*]
$\Delta^{21(22)}$, R = H, R^1 = OH, spergulatriol (**92**) [*61127-09-1*]

Molluscicidal saponins have been proposed as a means of controlling the spread of schistosomiasis in tropical countries through elimination of the snail vector *Biomphalaria glabrata* [10].

4. Animal Saponins

Marine invertebrates of the phylum Echinodermata are categorized into five classes [107]: *Holothuridea* (sea cucumbers), *Asteroidea* (starfish), *Echinoidea* (sea urchins, sand dollars), *Ophiuroidea* (brittle stars, basket stars), and *Crinoidea* (sea lilies, feather stars). Only members of the classes *Holothuridea* and *Asteroidea* produce saponins. Asterosaponins are based on a steroid cholestane system, whereas holothurins have a triterpenoid lanostane framework. Besides the common sugars listed previously, less common sugars encountered are the 6-deoxy compounds β-D-quinovose (qui) and β-D-fucose (fuc), both in their pyranose forms.

4.1. Asterosaponins

Hydrolysis of crude saponin isolated from starfish yields the steroid asterone (**93**) [107] together with asterogenol, the corresponding 20*S*-hydroxyl reduction product [108]. A noteworthy feature is the $\Delta^{9(11)}$ double bond. Asterone (**93**) is derived from the genuine sapogenins thornasterol A (**94**) and B (**95**) [109] via retroaldol cleavage.

Asterone (**93**) [*37717-02-5*]

R = H, thornasterol A (**94**) [*55897-77-3*]
R = CH_3, thornasterol B (**95**) [*55897-78-4*]

Most saponins from starfish are sulfated at the 3-β-OH group and glycosylated at the 6-α-OH moiety. Their sugar chains consist of five to six monomeric units, with branching at the second sugar. Examples are forbesides A, B, and C, isolated from *Asterias forbesi* and characterized as gal1 $\rightarrow$ 3fuc1 $\rightarrow$ 2gal1 $\rightarrow$ 4(qui1 $\rightarrow$ 2xyl)1 $\rightarrow$ 3qui-6-O-**94**-3-O-$SO_3^-Na^+$, qui1 $\rightarrow$ 2gal1 $\rightarrow$ 4 (qui1 $\rightarrow$ 2xyl)1 $\rightarrow$ 3qui-6-O-**94**-3-O-$SO_3^-Na^+$, and fuc1 $\rightarrow$ 2gal1 $\rightarrow$ 4(qui1 $\rightarrow$ 2qui)1 $\rightarrow$ 3(6-deoxy-β-D-xylo-4-hexosulopyranosyl)-6-*O*-**94**-3-*O*-$SO_3^-Na^+$, respectively [28].

Sapogenins with an epoxy function in place of the keto group in the thornasterol side chain [110] or penta- and hexahydroxylated cholestane ring systems [111] have been reported.

Uses. Biological activities reported for asterosaponins [112] include cytotoxicity to tumor cells and antiviral activity. However, the high toxicity of these compounds prevents their pharmaceutical use. Use as precursors for steroid synthesis [113] is not technically feasible.

4.2. Holothurins

Holothurins are similar to the asterosaponin glycosides isolated from sea cucumbers. They have a $\Delta^{9(11)}$ double bond, and are prone to yield artifacts. The genuine aglycone holothurigenol

Sapogenin	CAS registry no.	Δ	R	R^1	R^2

Figure 10. Holothurinogen-type sapogenins

(**96**) yields a $\Delta^{7,9(11)}$-diene elimination product on acidic hydrolysis.

Holothurigenol (**96**) [*72244-90-7*]

Aglycones are glycosylated at the 3-β-OH group with sugar chains containing two to six monomer units. In contrast to asterosaponins, hydroxyl groups on the aglycone system are not sulfated. Instead, hydroxyl moieties in the glycoside chain are methylated and sulfated.

Holothurin B, isolated from *Holothuria leucospilata*, was identified as qui1 $\rightarrow$ 2(Na^+ ^-O_3S--*O*-4′-xyl)-3-*O*-**96** [114], whereas holothurin A was shown to be CH_3-*O*-3′-glc1 $\rightarrow$ 3glc1 $\rightarrow$ 4-holothurin B [115].

Other examples are saponins derived from aglycones with linear side chains at C-20 (cf. Fig. 10). Bivittosides A through D are derived from **97** and **98** [116], echinosides from **99**, and holotoxins A and B from holotoxigenol (**100**) [117].

Sapogenins with a Δ^7 – instead of $\Delta^{9(11)}$ – double bond have been reported in *Cucumaria frondosa* [118] and *C. echinata* [119].

Uses. Although interesting biological activities have been reported (e.g., cytotoxicity to tumor cells [119] and positive inotropic and chronotropic action on atrial muscle [120]), the pharmaceutical use of holothurins is prevented by their severe toxic effects.

1. Introduction

1.1. Definition of Sealing Materials

Sealing materials, or sealants, (sometimes referred to as caulking materials) constitute a broad class of materials used to prevent the intrusion of water, air, and dirt into joints, holes, or gaps. Many of the gaps in question are "working" joints that open and close with changes in temperature. For this reason, most sealants are required to display adhesive properties so that they will adhere to the joint and maintain a complete seal. In fact, some types of sealant serve not only as a seal, but also to bind two materials together structurally. Sealants of the latter type are often called "adhesive sealants."

1.2. Performance Characteristics

There are many ways to classify sealants, but one of the most common addresses the sealant's ability to withstand joint movement. Among the first sealants developed were oil-based putties. These putties are often formulated with soybean or linseed oil, fibrous filler, calcium carbonate, gelling agents, and a catalyst. Such "low-performance" materials are very inexpensive, but generally effective only in joints with movements limited to $< 5\,\%$ of the total joint width. Some of these materials are still in use today, but generally only in applications entailing no movement, or as crack fillers. Because of their low cost they are in fact often misused.

"Medium-performance" sealants tolerate movements of $5 - 12.5\,\%$ of the joint width. Typical sealants applicable in this movement range are butyls, latex acrylics, and solvent acrylics, materials discussed briefly in Chapter 2.

"High-performance" sealants are designed for joints with movements $> 12.5\,\%$. These chemically curing elastomers include polysulfides, the best acrylics, urethanes, and silicones. Many such sealants can accept movements of $\pm 25\,\%$, and the best continue to perform satisfactorily with movement as great

10.1002/14356007.a23_499

as ±50 % or even +100 %/−50 %. High-performance sealants are the focus of this article. Note that the movement levels cited are as defined by ASTM C 719, which incorporates hot/cold cycles but tests a sealant only in its optimum condition (after 21 days of cure), not after the sample has been aged by weathering. ASTM C 719 is the only sealant-movement test used consistently throughout the United States, and thus provides a good test for comparison of performance (see also Section 1.3.3).

1.3. Specifications and Physical Properties

1.3.1. General Considerations

As the development of sealants has progressed, many types of specifications have appeared. The International Organization for Standardization is working toward a system of global specification. This has been adopted in Europe, but not yet in other parts of the world. In the United States, ASTM specification C 920 is commonly employed, whereas the Japanese Industrial Standard JIS A 5757 defines elastomeric sealants for industrial high-performance construction applications in Japan [1]. The standards themselves will not be discussed here, but their use is described in the reference cited.

Many physical properties of a sealant are subject to direct measurement. Some of the more important properties are described in the sections that follow for use later in this article.

1.3.2. Modulus of Elasticity

The term "modulus of elasticity" as used by sealant manufacturers refers to the secant modulus, a measure of the stress experienced by a sealant at a given strain. The modulus is very important because it reflects the force exerted by a sealant on an adhesive bond during movement. A high-modulus sealant transmits a high force to the bond, which may prove undesirable in the case of a weak substrate such as concrete. Although concrete is very strong in compression, it becomes quite weak if exposed to the tensile forces of a high-modulus joint sealant. For this reason, the modulus of a sealant must be closely matched to the strength of the substrate. Sealant failures involving high-modulus sealants on weak substrates (like concrete) actually reflect cohesive failures in the substrate itself at its surface, a direct result of the high stress transmitted to the substrate from the sealant as the joint opens.

Low-modulus sealants are gaining in popularity for construction joints (with the important exception of structural glazing) because with such materials less stress is imposed on the sealant, the substrate, and the bond line, maximizing the probability of a successful seal. Medium-to-high-modulus sealants are often used in applications in which the sealant must also serve as an adhesive. Structural glazing, which involves the relatively strong substrates glass and metal, is one such application.

When reviewing a manufacturer's modulus claims it is important to check actual force values generated by a given movement rather than relying only on a nondimensional specification like low, medium, or high. No such qualitative evaluations are presented in this paper because various companies use the terms in different ways. Modulus values from different manufacturers must in any event be compared with caution, since the actual values can vary significantly as a function of specimen size, shape, and the rate of strain.

1.3.3. Movement

The movement capability of a sealant describes the amount of displacement the sealant can withstand during extension and compression when placed in a joint modeling the final application. Since this test is specific to a particular substrate and sealant, it measures both the adhesive properties of the sealant to the substrate and the sealant's ability to stretch and recover. Movement is commonly expressed as "$\pm x\%$," where the positive value refers to extension and the negative value indicates compression. For example, a sealant with a +50/−25 % rating can be extended by 50 % or compressed to 25 % of the original joint width. Like modulus values, movement capabilities of sealants must be interpreted carefully. Movement capability is significantly affected by the nature of the substrate, cure time, curing conditions, temperature, and

rate of cyclic movement. One of the most severe movement tests specified in the United States is ASTM C 719, "Standard Test Method for Adhesion and Cohesion of Elastomeric Joint Sealants Under Cyclic Movement". This test exposes a sealant to several cycles of movement at 3.2 mm/h during a series of exposures to water and both high and low temperatures. In general, sealants with lower modulus values provide higher movement capabilities. Movement tests are among the most useful tests for sealants because they come close to simulating conditions to which the sealant will actually be exposed. However, a sealant manufacturer's movement claims must always be interpreted with caution. For example, a reported "50 % movement ability" may in fact be an alternative way of expressing "± 25 % movement." Movement claims presented in the absence of a test temperature may mean that the test was performed only at room temperature, and the sealant in question might not perform well under low-temperature conditions. Movement tests carried out according to the complete ASTM C 719 procedure indicate that a sealant has been tested under both hot and cold movement conditions.

1.3.4. Adhesion

One of the primary functions of a sealant is to adhere or stick to the substrate being sealed. Without adhesion, the sealant would fail, causing the joint to leak. Although there are many so- called general-purpose sealants, no single sealant provides good adhesion to all substrates. Typically, a given sealant is designed for a specific market and a few target substrates. Adhesion to other substrates can sometimes be achieved through the use of a primer, but sealants are generally designed to be self-priming. Adhesion can be tested in a variety of ways, but the best procedure is to measure adhesion in a test joint that models as closely as possible the proposed application and the anticipated weather conditions. Accelerated weathering with water, heat, and ultraviolet (UV) light can give a useful preliminary indication of the adhesion life-expectancy of a sealant. Rapid data collection is possible with accelerated tests, but devising the proper accelerated model, one that will give an accurate prediction of sealant performance, can unfortunately be quite difficult. Sealant suppliers often prefer simply to cite previously successful sealing applications, leaving the customer to decide whether the proposed application is analogous. Certain adhesion tests are also specific to individual sealant manufacturers. Typically, such tests specify a particular substrate, sealant, and type and length of weathering exposure, as well as what is considered to be acceptable performance. In order to model true sealing applications, tests of this type should always include some indication of movement value.

1.3.5. UV and Weathering Stability

Most sealants are subject to years of exposure to sunlight, heat, cold, rain, wind, and pollutants. Sealants can deteriorate on the basis of several different mechanisms, but ultraviolet radiation from sunlight is one of the more common destructive agents. Upon exposure to sunlight some urethanes and polysulfides develop surface cracks that may penetrate the seal during joint movement and with continued exposure. Polysulfides and silicones generally harden with age, although the extent of hardening varies widely. Some may harden within 5 or 10 years, while others may still perform at greater than 50 % of their original capacity after 30 years.

Sealants are usually exposed to accelerated weathering tests involving heat, water, and UV radiation, but there is significant disagreement over the best way to extrapolate accelerated weathering data to actual life expectancy. Nevertheless, these data may provide the only way to predict longevity for a particular product. Weathering data can often be obtained either from the sealant manufacturer or from architects knowledgable in construction sealants. In general, such accelerated data should be based on thousands of hours of testing.

1.3.6. High-Temperature Stability

In construction applications, elastomeric sealants may need to withstand temperatures as high as 90 °C on the dark- colored, south-facing walls of a building. Other industrial applications also subject sealants to various extremes of heat. Depending upon the application, the

heat stability of a particular sealant may be a critical factor. Long exposure to heat causes some sealants to harden, while others revert to a putty-like paste. Most manufacturers provide upper limits for the service lives of their sealants, and individual sealants often have upper usable temperature limits below the highest temperatures predictable in certain applications. It is therefore important to take the manufacturer's recommended temperature limit carefully into account when a sealant is selected. One should also consider the probable duration of anticipated temperature extremes. For example, some sealants can be exposed successfully to high temperature over the course of one week, but not for a month. Knowledge of the duration of a likely stress is as fundamental in choosing usable sealants as knowing the severity of that stress.

1.3.7. Low-Temperature Flexibility

Some sealants are also subject to harsh winter temperatures and winds. While most sealants remain flexible to $-30\,^{\circ}C$, the extent of this flexibility can vary. For applications involving joint movement at low temperature, tests should be conducted to verify the ability of a particular sealant to perform well at the specified temperature. It is crucial that low-temperature testing be carried out on thoroughly cured sealants with a test such as ASTM C 719. Partially cured sealants may successfully pass a test such as this in the laboratory, but fail on the job once they have fully cured and reached their ultimate modulus. If low-temperature durability is important and time permits, sealants should be cured for six months prior to low-temperature testing.

1.3.8. Reversion

High-performance elastomeric sealants "cure" after extrusion to form an elastic rubber. The modulus of this rubber is not constant, but changes as a function of the conditions to which the sealant is exposed. High-performance sealants generally change more slowly than low- or medium-performance sealants. Under certain conditions, a cured elastomer may "revert," or return to a soft, pasty consistency resembling the uncured sealant; other sealants may become stiff and hard. Some sealants survive for 2 years, some 5 years, some 10 years, some 20 years, and some much longer before modulus changes prevent them from performing satisfactorily. Vast differences exist even within a single generic class of high-performance sealants. For instance, some urethanes become hard within a year or two as a result of weathering in sunlight (although their behavior in the shade may be quite different), while others may retain a high fraction of their joint movement capacity for several years. Other urethanes cure initially to an elastomer, but then become soft and mushy after one or two years of exposure to direct sunlight [2]. This is the phenomenon referred to as reversion. On the other hand, certain two-part, mix-on-site sealants become soft and mushy simply because they were not mixed in the correct ratios. The difference between these two rather similar manifestations – one from a poorly cured material, the other due to reversion – is that the reverted sealant was once a good rubber that later deteriorated, while the incorrectly mixed sealant never fully achieved the rubbery state. The former represents a product problem, but the latter is an application problem.

1.3.9. Staining

Staining is a concern with all sealants. Noncuring butyl materials, some reverting urethanes, certain polysulfides, and some silicones are among the sealants known to discolor glass and other surfaces. Coated glass, porous ceramics, and white marble are especially prone to surface staining. Testing is often carried out prior to large sealing jobs to ensure that the proposed sealant and substrate are compatible. ASTM C 510 and D 2203 are screening tests useful in establishing whether a particular sealant will stain a substrate [3]. As with other performance criteria for sealants, manufacturers are prepared to provide the user with staining data upon request.

A related concern is surface contamination caused by a sealant. Paint shops are very wary of sealants, because surface contamination may interfere with the adhesion of paint to a surface undergoing treatment. Silicones for use in the automobile industry are often specially formulated to be free of traces of volatile components

that might otherwise affect paint adhesion to a substrate.

2. Medium-Performance Sealants

2.1. Butyl Sealants

Butyl sealants constitute a class of medium-performance sealants that includes moldable, preformed butyl tapes as well as hot-applied butyl, solvent-release butyl, and polyisobutylene sealants. Butyl rubber is a copolymer of isobutylene with 15 – 45 wt % isoprene. Polyisobutylene (PIB) is produced by the polymerization of isobutylene, $H_2C{=}C{-}(CH_3)_2$ (→ Butenes; → Polyolefins, Chap. 3.;→ Polyolefins, Chap. 4.; → Rubber, 3. Synthetic). These two materials have been used as sealants since the 1930s. Both contain fillers, typically carbon black, zinc oxide, clays, or silicas. Tackifiers such as the pentaerythritol ester of rosin are also incorporated. Solvent-release butyls commonly contain cyclohexane to plasticize the sealant and facilitate hardening as the solvent evaporates [4].

Preformed butyl tapes re completely solid sealants used in the glazing industry to bond glass to aluminum. They do not shrink, but have a short service life: up to ten years depending upon the environment. *Hot-applied butyls* find particular application in the glazing industry. They are applied at 150 – 204 °C, and form somewhat elastomeric sealants as they cool to room temperature. *Solvent-release butyls* are low in cost and generally provide good adhesion. However, they are limited to about 10 % movement, display moderate shrinkage, and can stain certain substrates. *Polyisobutylene*, a solid sealing material, is used as the primary moisture – vapor seal in the construction of dual-sealed insulating glass units. Low moisture – vapor transmission is what makes polyisobutylene the sealant of choice for this purpose. Secondary seals in insulating glass are typically fabricated from silicone, urethane, or polysulfide. Solvent-release forms of polyisobutylene are also available, but these have the same limitations as solvent-release butyl sealants. Because of their low cost, butyls have become the sealants of choice in the mobile home industry and many other cost-sensitive markets where longevity is not demanded.

2.2. Latex Acrylic Sealants

Latex acrylic sealants were introduced in the late 1960s. Very high molecular mass, low viscosity polyacrylates are prepared by a batch emulsion polymerization process in which monomer, water, surfactants, and an initiator are added to a reactor and polymerized until the acrylic monomer is depleted (→ Polyacrylates, Chap. 3.1.). The maximum level of solids is 60 – 65 %. Above this point viscosity increases significantly and latex stability is poor. Compounding into sealants is accomplished by adding fillers, a freeze – thaw stabilizer, a thickener, and an adhesion promoter [5]. Both clear and pigmented forms are available.

Latex acrylics are easy to apply, and they can be cleaned up with water. Most are low in volatile organics, paintable, and inexpensive, and some provide good adhesion. On the other hand, they are subject to considerable shrinkage, and their modulus changes significantly with temperature [6]. Movement capability is generally near ± 12.5 %, although the literature claims that some formulations achieve ± 25 % movement capability. Latex acrylic sealants are very popular in residential construction and in the consumer market as a result of relatively low cost and ease of application and clean-up.

Many "siliconized" latex acrylics are also available, but they are similar or even identical to conventional latex acrylics with no distinctive silicone characteristics.

2.3. Solvent-Release Acrylic Sealants

Solvent-based acrylic polymers, like latex acrylics, are also produced by batch polymerization, but a solvent is used in place of water and surfactants. The molecular masses of solvent-based acrylic polymers are lower than those of latex acrylic polymers due to a high inherent viscosity. However, the solids content is higher, typically in the range 80 – 83 %. Because these materials contain a considerable amount of solvent and (typically) at least some low molecular mass reactable species, they are able to penetrate dirt and grease and still develop adhesion,

unlike other sealants, which require clean surfaces for optimal adhesion. The UV (sunlight) durability of acrylics is quite good, and their cost is moderate. The high level of solvent and the presence of relatively volatile acrylic components does lead to considerable odor, however, so these sealants are generally limited to outdoor applications. Sealants in this category tend to become permanently deformed as a result of both extension and compression, and they become stiff in cold weather. This restricts their use in high-movement joints. Joint movement capability for solvent acrylics is low, typically 12.5 % maximum.

While all medium-performance sealants are subject to a variety of modes of failure, the most common cause of failure for this group of sealants is hardening. Hardening is usually caused by a gradual loss of plasticizer, together with some oxidative degradation.

3. Polysulfides

3.1. Composition

The basic components of a polysulfide sealant are polymer, plasticizer, filler, curing agent, accelerators/retarders, thixotropes, and adhesion promoters (→ Rubber, 3. Synthetic, Chap. 5.3.1.2.). The polymer backbone may have any of several structures, but most cure through reactions at the terminal mercaptan ends. Several types of polysulfide polymers are illustrated in Figure 1.

Conventional polysulfide polymers are available in molecular masses ranging from 1000 to ca. 8000, with cross-link densities of 0.05 – 2.0 mol %. Modulus and hardness values for a polysulfide sealant are controlled mainly by the extent of cross-linking.

Although condensation or addition reactions can also be used to cure polysulfide sealants, the most common approach is oxidation. Several different oxidative curing agents are employed. Among the most common are lead dioxide, calcium peroxide, zinc peroxide, manganese dioxide, and cumene hydroperoxide. The choice of a specific curing agent is often dictated by the intended application, as shown in Table 1. Some curing agents lead to unwanted byproducts that can affect the mechanical properties of the cured polymer, which requires control by a second additive. For example, lead dioxide curing can result in the formation of an undesirable lead mercaptide species, but this can be eliminated by heating or introducing a small amount of elemental sulfur.

Table 1. Polysulfide curing agents [7]

Curing agent	Application
Lead peroxide	building/construction sealants
Manganese dioxide	improved heat and UV resistance – aircraft and insulating glass
Calcium peroxide	one-component sealants (activated by exposure to moisture)
Inorganic chromates	improved heat resistance – aircraft sealants

The curing rate of a polysulfide sealant can be influenced through the use of accelerators or retarders. Such *cure-rate modifiers* usually work by altering the pH of the sealant, and may change the cure time for a two- component sealant by a matter of minutes or even days. In general, acids are used to reduce the cure rate, while bases accelerate the process. Table 2 lists several cure-rate modifiers for common curing agents.

Table 2. Polysulfide sealant cure-rate modifiers [8]

Curing agent	Retarder	Accelerator
PbO_2	stearic acid metallic stearate	sulfur
CaO_2		water
ZnO_2	sulfur	amines
MnO_2	stearic acid	bases
Cumene hydroperoxide		copper ions, bases

Fillers are added to polysulfide sealants to reinforce, extend, and control the rheology of the system. Common fillers include ground calcium carbonate, precipitated calcium carbonate, furnace or thermal carbon black, and calcined clay. The particle size of a filler plays an important role in determining the extent of reinforcement and the resulting viscosity. The pH of the filler is also an important factor, because it can have an impact on the cure rate and the final stability of the cured sealant. Some fillers, such as the calcium carbonates, are often coated with treating agents as a way of reducing their effect on the pH of the system.

Plasticizers are added to polysulfide sealants to extend the system and lower the modulus. These must be compatible with polysulfide polymers and low in volatility to minimize shrinkage

Figure 1. Examples of various types of polysulfide polymers

of the cured sealant. Commonly used plasticizers include butyl benzyl phthalate, octyl benzyl phthalate, dibutyl phthalate, hydrogenated terphenyl, chlorinated hydrocarbons, and modified styrene.

Although polysulfides display some inherent adhesion to common construction substrates, adhesion-promoting additives are typically introduced to generate the high levels of adhesion required in a modern sealant.

3.2. Properties

Modulus of Elasticity. Polysulfide sealants are subject to a high degree of stress relaxation. As a result, measured modulus of elasticity values are dependent upon test-specimen size and testing rate. Stress relaxation can be beneficial, because it allows a polysulfide sealant to stretch without transmitting excessive force to the sealant – interface bond line. However, it also reduces a polysulfide's ability to recover after the stress is removed. This slow recovery characteristic can lead to problems in rapidly cycling joints. Stress relaxation also limits the use of polysulfides in compressive gaskets [8].

Movement. With proper formulation, many polysulfides can accommodate joint movement of $\pm 25\,\%$, which is adequate for most construction joints. Joints subject to rapid cyclic movements can pose a problem for polysulfides if the cycling rate exceeds the rate at which the sealant can recover. Rapid movement in this sense can result in wrinkling or cohesive failure of the sealant [9].

Adhesion. As in the case of other common sealants, additives are typically introduced into polysulfides to ensure adhesion to specific substrates. Phenolic resins, epoxy- and mercapto-functionalized silanes, and epoxy resins are typical additives that improve adhesion to glass, aluminum, and steel. Each of these promoters has the ability to bond chemically to mercaptan groups in the polymer and to reactive sites at the substrate interface [10]. Other substrates, such as masonry or wood, often require primers.

UV and Weathering Stability. Performance in this respect can vary widely among different formulations and brands, making it difficult to characterize the stability of a "typical" polysulfide. Low-quality polysulfides show surface crazing or "alligatoring" after weathering, whereas higher quality polysulfides have successfully sealed certain structures for periods of 10 – 20 years. While the weatherability of polysulfides is not as good as that of silicone, it is adequate for many types of outdoor exposure. All polysulfides are subject to some UV damage; although they can be used for glazing applications in which the bond line is protected from sunlight by a mullion or corner, they are never used in structural glazing situations where the sun shines through the glass onto the bond line.

High-Temperature Stability. In general, polysulfides are intended for use below 100 °C (typically 70 °C), and their hardness can in-

crease with time or heat aging. If exposure to high temperature is contemplated, tests should be conducted to establish the heat stability of a particular sealant at the anticipated service temperature.

Low-Temperature Flexibility. Polysulfides become stiffer at low temperature, but hardening is not significant above − 34 °C.

Chemical Stability. Polysulfides show high resistance to chemicals, heat, oils, and solvents, leading to reliable long-term adhesion in applications involving exposure to these agents. The solvent resistance of polysulfides is the key to their wide use as fuel-tank sealants in the aircraft industry and in many other fuel- containment applications.

Staining. Staining is generally not a problem with polysulfides. However, certain phenolics that are added as adhesion promoters have caused staining problems on masonry.

Modes of Failure. Typical modes of failure for polysulfide sealants vary with the application. In glass and glazing applications, a common cause of failure is destruction of the bond to glass by direct or reflected sunlight. A second failure mechanism affecting many polysulfide sealants is hardening due to oxidation and loss of plasticizer. In joints subject to considerable movement, compression set is a serious problem, especially with the very slow- curing polysulfides. In construction applications, installation defects, such as failure to use a recommended primer, or poor surface cleaning, can result in adhesive bond failure.

3.3. Advantages, Markets, and Limitations

A major advantage of polysulfides is their excellent chemical resistance. This property has led to applications in aircraft fuel-tank sealing and in special construction joints where chemical resistance is important. Polysulfides are among the materials used to seal spill- containment areas for airports.

The insulating glass industry, especially in Europe, is another large consumer of polysulfides. Mercaptan-terminated polyoxypropylene sealants, a special category of polysulfides, also find use as insulating glass sealants. They show relatively good weatherability characteristics and generally low inert gas transmission rates in comparison with conventional polysulfides. This is important, because inert gases such as argon are finding increasing use to improve insulating values in insulating glass units.

3.4. Major Suppliers

Major U.S. suppliers of polysulfides are Chem-Rex, Morton International, Pecora, Products Research and Chemical, and Tremco. In Europe, major suppliers include Chemetal, Evode, Expandite, Kommerling, Le Joint Français, Products Research and Chemical, Servicized, and Teroson [11].

4. Urethanes

4.1. Composition

The three major components in a polyurethane (or urethane) sealant are polymer, filler, and plasticizer (→ Polyurethanes). Isocyanates are the basic starting materials for forming urethane polymers. These react with compounds containing active hydrogen, including alcohols, amines, acids, and water, as illustrated by the example below:

$$\underset{\text{Isocyanate}}{R-N=C=O} + \underset{\text{Alcohol}}{R'-OH} \longrightarrow \underset{\text{Urethane}}{R'-O-\overset{\overset{\displaystyle O}{\|}}{C}-NH-R}$$

Isocyanates are made by the phosgenation of amines, and are available in both aromatic and aliphatic forms. To reduce costs, most urethane sealants are prepared with aromatic isocyanates despite the fact that they are subject to yellowing and UV (sunlight) instability. Aliphatic isocyanates are used in special sealants in which yellowing might prove a problem, and where increased stability is necessary. Aliphatic isocyanates normally react more slowly and are usu-

ally more expensive, but they show improved resistance to hydrolysis and thermal degradation [12].

The starting isocyanates are not present in free form in urethane sealants but rather are incorporated into oligomers, commonly called "prepolymers", which result from the reaction of a difunctional isocyanate with a hydroxy-containing compound. Polyesters were common components of the early urethanes, but the most widely used hydroxy compounds today are hydroxy-terminated polyethers, made by the base-catalyzed addition of propylene oxide (PO) to di- or polyfunctional alcohols or amines. Typical polyfunctional alcohols used for this purpose are propylene glycol, glycerol, and trimethylolpropane. The structure of a typical polyether used in polyurethane sealant formulation is shown below:

The molecular mass of the polyether component can vary over a wide range, from ca. 440 to > 6000. Both diols and triols are available with this spectrum of molecular masses.

The first step in preparing a urethane sealant is reaction of the diisocyanate with the polyether. Normally one mole of diisocyanate is used for each mole of hydroxyl groups, to produce a polymer with a terminal isocyanate group, as illustrated below:

The isocyanate ends of the resulting prepolymer are still reactive with respect to active-hydrogen containing materials. A *two-part urethane* sealant can be cured to an elastomer by mixing it with, for example, 1,4-butandiol, leading to a cross-linked network in the cured elastomer. *One-part urethanes* are more complicated. Reaction of the terminal isocyanate groups with water vapor from the air produces carbon dioxide, which causes bubbling in the sealant. One method of solving this problem involves reacting the prepolymer with phenol and then mixing the resulting "blocked" prepolymer with diketimine. When exposed to moisture, the diketimine is transformed into a diamine with the release of 2-butanone. The diamine then cleaves the bond between phenol and the urethane, causing a chain-extension reaction to occur [13].

As implied above, isocyanates are very reactive with water, and the urethane formulator must be very careful to exclude water and to predry all the components of the formulation. Too much water can reduce shelf-life or cause a formulation to gel. One approach to eliminating moisture during formulation is the addition of quicklime (calcium oxide), which reacts with water to form calcium hydroxide. This reaction is quite slow, and can require hours to occur. It is also reversible, and small amounts of water may reform at a later time. Too much lime can also be detrimental, because it can reduce shelf-life and cause poor weatherability.

Plasticizers are often added to urethane sealants to reduce the viscosity of the formulation. Lower viscosity simplifies handling of the sealant. It also leads to a lowering of the modulus, and in some cases the elongation potential increases as well. Plasticizers are normally introduced in the 5 – 20 % range; typical examples include phthalates, phosphates, chlorinated hydrocarbons, and aromatic oils.

Some urethane sealants contain coal tar or asphalt as extenders, both to reduce cost and to add moisture-barrier properties. Coal tar contains active hydrogens, another factor that must be taken into account by the formulator. Also, tar-modified urethanes display rather poor UV resistance.

Common fillers in urethane sealants include calcium carbonate, talcs, clays, and fumed or precipitated silica. The choice of filler depends

on the desired final properties and anticipated uses of the sealant. Electrical properties can be significantly affected by a filler, as can modulus and elongation, since fillers can be either reinforcing or nonreinforcing.

4.2. Properties

Modulus of Elasticity. The modulus of elasticity of a urethane sealant is influenced by the prepolymer type, isocyanate functionality, plasticizer level, and filler type and surface area. Unless specially plasticized, most urethanes have a rather high modulus of elasticity and are very tough and tear resistant. This is one reason for their use in high sealant-abuse areas, such as sidewalks and parking garages. Unfortunately, a high modulus can also limit a sealant's joint movement capability. Unlike polysulfides, the modulus of a urethane sealant is not affected by the rate of testing, a consequence of the high recovery ability of urethanes. Good urethane sealants yield recoveries of 70 – 90 %, which is better than polysulfides but in general not as good as silicones.

Movement. One- and two- component urethanes display a movement capability of as much as ± 25 %, with some manufacturer's literature claiming even higher values.

Adhesion. Urethane sealants have inherent adhesion capabilities with respect to most common substrates. However, this adhesion is often destroyed by exposure to water. Adhesion is improved by the use of adhesion promoters or primers. The most common adhesion promoters for urethane sealants are silane coupling agents. Epoxy-, amino-, and mercaptosilanes have been successfully used due to their dual reactive nature. The alkoxy ends typically react with surface hydroxy groups of the substrate, while the epoxy, amino, or mercapto ends react with the urethane polymer. Most urethanes show an increase in modulus with age. For this reason the adhesion must be tenacious and durable, since a high degree of stress is placed on the sealant/substrate bond, and the stress becomes greater as the sealant ages and hardens.

UV and Weathering Stability. While not as UV-resistant as silicones or acrylics, urethane sealants can be formulated to show reasonable UV resistance by the addition of UV stabilizers and antioxidants. Life expectancies for most urethane sealants range from 5 – 20 years depending on the application and exposure. If protected from direct sunlight, urethanes have long, useful lives in many areas of application, such as the automotive industry and construction. If not protected from sunlight, urethanes may develop surface cracks that can propagate through the sealant at an actively moving joint, leaving an open, unsealed joint. As with all sunlight-sensitive sealants, it is very important with urethanes to provide a sufficiently deep (thick) sealant bead so that considerable time will elapse before a crack traverses the entire depth.

High-Temperature Stability. Most urethane sealants are used in applications with high-temperature limits $< 100\,^{\circ}$C, and temperatures in excess of 80 °C can often be quite detrimental.

Low-Temperature Flexibility. In general, urethanes remain flexible to $-40\,^{\circ}$C. As with any sealant, testing is important to ensure that a particular sealant will satisfy low-temperature requirements.

Reversion. No single urethane can be regarded as typical. All are unique. With exposure to weather some tend to harden, while others become quite soft under the same conditions. Heat and moisture may exert some influence, but the primary influence in aging is ultraviolet (sunlight) radiation. Therefore, UV absorbers and UV-blocking pigments are very important. Differences in the type and content of UV stabilizers are one reason for the observed wide variation in urethane performance. Under certain conditions of temperature, light, and humidity, some urethanes revert to very soft or mushy sealants; others remain intact, and certain types even become quite hard.

Staining. Staining is not normally a problem with urethanes, apart from those that undergo reversion. Even with reversion any urethanes or plasticizers that reach the surface tend to be degraded and eliminated from the sealant. Thus,

except in cases where the sealant becomes very soft, urethanes are considered to be nonstaining.

Modes of Failure. Failure with urethane sealants is very much product- and application-dependent, although certain failure modes are more prevalent than others. One common cause of failure in direct sunlight is the formation of surface cracks, which can propagate completely through the seal in an active, moving joint. Another general mode of failure is sealant hardening. In this case, the sealant rarely tears, but joint movement places so much stress on the bond that adhesive bond failure occurs, or there may be cohesive substrate failure (in concrete, for example).

As mentioned previously, urethanes react readily with moisture to produce carbon dioxide. Bubbling that occurs during sealing with a urethane is often a result of moisture present on the substrate [14].

4.3. Advantages, Markets, and Limitations

Urethanes can be formulated to display a wide variety of properties, including modulus values ranging from very low to very high. In general they show good chemical resistance. Urethanes are tough and abrasion resistant, making them very useful in traffic-bearing joints such as those found in parking decks. Much perimeter building sealing is accomplished with urethanes. Another major market for urethane sealants is the automotive sector. Thus, urethane sealants are commonly used to bond windshields to metal frames (using primers) and to seal taillights. Curtain-wall glazing is generally carried out with silicone rather than urethanes due to some loss of urethane adhesion from UV exposure. Specially formulated urethanes can be used in insulating glass, but not in places where sunlight is likely to shine on the bond line. Urethanes are also not recommended for use where the service temperature will exceed 80 °C, and dry substrates are required to prevent bubbling.

4.4. Major Suppliers

Major suppliers of urethane sealants in the United States include ChemRex, Mameco International, Pecora Chemical, Products Research and Chemical, Sika, and Tremco [15].

5. Silicones (→ Silicones)

5.1. Composition

Silicone sealing materials are classified according to the three principal mechanisms by which they cure: moisture-cure sealants, silicone latex sealants (which cure by releasing moisture), and addition- curing sealants, which do not release any volatiles. The silicone latex referred to here is a true silicone based on silicone polymers, and should not be confused with siliconized latex acrylic sealants. Siliconized latex acrylic sealants contain less than 2 % silicone, and have all the characteristics of ordinary acrylic sealants.

Moisture- cure silicones are by far the most common silicone sealing materials. They consist of a silicone polymer, a filler, and a moisture-reactive silicone cross-linker. Depending upon the cross-linker used, a catalyst may also be needed. Most polymers used in silicone sealants are polydimethylsiloxanes, with repeating dimethylsilicon and oxygen units. The general structure of these polymers is shown below:

Although many different terminal groups can be attached to such a polymer, most sealant polymers invoke hydroxy groups, through which curing of the silicone sealant takes place. The viscosity of the polymers can range from < 100 cp to > 100 000 cp.

Specialty polymers can be produced to meet specific performance requirements. For example, the brittle-point of a silicone sealant can be lowered from − 65 °C to − 110 °C for aerospace applications by the introduction of diphenylsiloxy groups. Sealants that will be exposed to jet aviation kerosene or gasoline are made low-swell by attaching 1,1,1-trifluoropropyl groups to each silicon atom [16].

Moisture-curing silicones generally require moisture-reactive cross-linkers to convert the paste-like uncured sealant into an elastomer. Many different silicone-based cross-linkers are used. However, most have three (trifunctional) or four (tetrafunctional) reactive ends that react with both moisture in the air and the hydroxyl ends of the silicone polymer to cross-link the sealant. This cross-linking reaction in turn releases a hydrolyzable group, which diffuses out of the sealant. Often an organometallic condensation catalyst is added to accelerate the cross-linking reaction, although some cross-linkers react rapidly without a catalyst. Common catalysts are stannous octoate (where "octoic acid" is an industrial product consisting of eight- carbon acids), tin carboxylates, and organotitanates.

Several important cross-linkers and the corresponding leaving groups are listed in Table 3.

The cure of these moisture-reactive cross-linkers is dependent upon moisture diffusing into the sealant and the byproduct diffusing out. This diffusion- controlled process causes a cured elastomer skin to form on the exposed sealant surface, which then progresses inward. Due to their moisture-reactive nature, silicone sealants must be compounded in the absence of atmospheric moisture.

The siloxane polymer network is quite weak if cured alone, so it is reinforced with various inorganic fillers. Fumed silicas and carbon blacks are often used to prepare high-strength sealants. Sealants that do not require high strength are made with low- or nonreinforcing fillers such as ground calcium carbonate, ground quartz, diatomaceous earth, and various clays. A wide range of rheological properties can be obtained, from nonslump to self-leveling. Moisture- curing silicones are the most widely used and best known of the silicone sealants.

The choice of a particular sealant is often dictated by the nature of the leaving group. The most common leaving group is acetic acid, leading to a vinegar odor, but acetic acid is corrosive to some surfaces. For this reason other, more neutral leaving groups are gaining in popularity. Nonacid cures should always be specified for use on reactive surfaces such as concrete, marble, zinc, or copper.

A second group of silicone sealants consists of the *silicone latex* or *water-based silicones.* These are relative newcomers compared to moisture- curing silicones. A sealant of this type is basically a silicone-in-water emulsion that cures through evaporation of the emulsifying water. It is prepared by first emulsifying a low molecular mass siloxane polymer and then polymerizing it to the desired degree. Emulsion polymerization permits the preparation of very high molecular mass polymers with low viscosity. A cross-linker is added next, along with a condensation catalyst. In contrast to moisture-curing silicones, cross-linking in silicone latex occurs during manufacture. The cross-linker is typically of the $R'\text{-}Si(OR)_3$ configuration, and must diffuse through the aqueous phase into the siloxane in order to react with the polymer. The pH of the aqueous phase must be carefully controlled to prevent the cross-linker from reacting with water before contacting the siloxane phase. Fillers and freeze – thaw stabilizers are also added to complete the compounding of a silicone latex sealant [17].

The advantages of a true silicone latex are similar to those of an acrylic latex. It can be applied to damp surfaces, contains relatively little volatile material, and is subject to very easy clean-up and application.

Addition- cure silicones are generally based on the platinum- catalyzed reaction of a polymeric silicon hydride with a vinyl group attached to a silicone polymer:

This vulcanization can be accelerated by heat, causing cure to occur within minutes in deep section. No byproducts are produced by this particular cross-linking reaction. Addition- cure silicones are used mainly for molding, encapsulation, and sealing applications. Buildings with penetrations through floors and walls that must be sealed with fire-rated materials are often sealed with addition- cure silicones. The primary advantages of addition- cure silicones are a rapid deep-section cure rate, cure in the absence of air, negligible amounts of volatile species, and no

Table 3. Common silicone cross-linkers and leaving groups

Cross-linker	Formula	CAS registry no.	Leaving group
Methyltrimethoxysilane	$CH_3Si(O-CH_3)_3$	[*1185-55-3*]	methanol
Methyltriacetoxysilane	$CH_3Si(O-\overset{\overset{\displaystyle CH_3}{\vert}}{C}=O)_3$	[*4253-34-3*]	acetic acid
Methyltri(methylethylketoxime)silane	$CH_3Si(O-N=C\begin{matrix}CH_3\\C_2H_5\end{matrix})_3$	[*22984-54-9*]	2-butoxime $(CH_3)(C_2H_5)C=N-OH$
Vinyltris(isopropenyloxy)silane	$CH_2=CHSi(O-\underset{\underset{\displaystyle CH_3}{\vert}}{C}=CH_2)_3$	[*15332-99-7*]	acetone

shrink with thick sections. The disadvantages of this type of silicone are sensitivity to contamination and problems with adhesion to some surfaces.

5.2. Properties

Modulus of Elasticity. Of the high-performance elastomeric sealants, silicones offer the widest modulus range available. Low-modulus silicones can be formulated with high molecular mass polymers containing a high level of plasticizer. However, this approach to low modulus can lead to staining with certain substrates. A second approach is to use a chain extender in combination with a cross-linker [18]. Reaction rates must be carefully matched to ensure the successful cure of a low-modulus sealant. In either approach, nonreinforcing fillers are added to keep the modulus low. Low-modulus silicones are commonly used in construction applications involving concrete. As noted previously, concrete has a low tensile strength, and high-modulus sealants can be a cause of cohesive failure. Very-low-modulus silicones are fast becoming the sealants of choice in substrate-sensitive environments and in almost all applications with very large joint movements.

High-modulus silicone sealants are prepared with relatively large amounts of highly reinforcing fillers, such as fumed silica. Tetrafunctional and trifunctional cross-linkers also contribute to an increased modulus. These sealants are used for applications in which adhesive seals are important, e.g., auto windshield applications, form-in-place gaskets, auto headlights, and appliance sealants.

Movement. Silicone sealants can be formulated to survive movements of +100/−50 %,thereby surpassing the qualities of other elastomeric sealants. Low-modulus sealants typically show the highest movement capability. Indeed, low-modulus silicones set the industry standard to which all other sealants are compared for movement ability in joints. The high movement ability of low-modulus silicones is a primary reason for their selection in remedial applications to seal joints with greater movement than can be tolerated by conventional sealants. Not all silicones are low modulus/high movement materials, however, and an appropriate sealant must be carefully selected for each application. Some applications, such as insulating glass secondary sealants, require high-strength, low-movement sealants, and thus a quite different formulation.

Adhesion. The adhesion characteristics of silicone sealants vary widely. Some general-use silicone sealants provide unprimed adhesion to all the usual construction and industrial surfaces. Such sealants generally contain one or several silane coupling agents to enhance adhesion to various surfaces. Formulators have access to many silane coupling agents, and a proper choice is essential for optimum performance. With some silicones a primer is required to ensure adequate adhesion on certain surfaces.

Addition- cure silicones can be formulated to provide very little inherent adhesion, and for this reason they are often used in molding or encap-

sulation applications in which release properties are important. An example is the encapsulation of electrical parts, where easy removal of the sealant is desirable in case the part must be repaired or modified. Adhesion is improved by the use of primers or proprietary adhesion promoters. Silicone latex sealants offer good adhesion, although it is generally inferior to that of moisture- curing silicones.

Silicones, like most other sealants, are usually inappropriate for applications in which the sealant is continuously submerged in water. A few exceptions exist, but the sealant supplier should be consulted before any attempt is made to seal a wet environment.

UV and Weathering Stability. Because silicones do not absorb UV radiation, they are not subject to degradation in sunlight. Accelerated UV-weatherometer exposures of 20 000 hours are common with no surface cracking. For this reason, silicones are frequently the sealants of choice for construction applications, and almost always for glazing applications in which sunlight will directly or indirectly reach the seal. This UV stability is a result of the absence of unsaturation in the silicon – oxygen backbone of the polymer. Extreme stability of this type is essential in structural glazing applications (i.e., in buildings with all-glass surfaces), where the sealant is the adhesive that actually holds the glass to the building. Indeed, silicones are the only materials permitted for structural glazing in which the sealant will be exposed to direct or reflected sunlight.

High-Temperature Stability. Silicones provide the greatest heat stability of any available class of elastomeric sealants. Industrial grades of silicone sealants can withstand temperatures of 160 –205 °C in air for a year without significant change in their properties [19]. A major contributor to this thermal stability is the polymer's silicon – oxygen backbone, but stability is also influenced by thermal stabilizers, fillers, and vulcanization catalysts. Heat stability is important in oven gaskets, appliances, and many industrial applications. Dark- colored, south-facing buildings also experience temperatures exceeding the 80 °C limit of most other sealants, and the heat stability of silicones makes them suitable for this application as well. While most silicones tolerate 80 – 100 °C very well, only a few survive for extreme lengths of time at temperatures > 200 °C.

Low-Temperature Flexibility. Siloxane polymers provide several important low-temperature advantages. Because the viscosity of the polymer changes only slightly at low temperature, extrusion of uncured sealant from cold cartridges is only slightly affected. The low-temperature flexibility of the polymer also permits the cured sealant to remain flexible to − 54 °C, and specialty polymers extend this low-temperature flexibility even further. More important, silicone modulus values change only slightly at low temperature, in contrast to other sealants. The brittle point of a silicone sealant can be lowered from − 65 °C to − 110 °C by the addition of diphenylsiloxy groups, a common expedient in aerospace applications.

Reversion. Silicones are extremely stable under normal weathering conditions, and show little change or drift in their properties, although some silicones prepared by tin carboxylate catalysis may revert at temperatures > 80 °C and if confined. Reversion due to cleavage of the silicon – oxygen bond can occur if a silicone is exposed continuously to strong acids or bases. Strong acids can also attack silicones that contain marble fillers.

Staining. Staining is the most widely cited flaw with respect to silicone sealants, but the e tent of staining varies considerably as a function of product and surface. Staining is most likely to be a problem with certain porous substrates, especially if the silicone contains low molecular mass nonreactive silicone plasticizers. Testing is often undertaken prior to sealing a large construction job to ensure that staining of the substrate will not occur.

Modes of Failure. Silicones have exceptional weatherability, so many of the failures actually encountered with these products are caused by loss of adhesion, usually because the sealants have such long lifetimes that they outlive the adhesive bond. Bond life is dependent on both the environment and the nature of the silicone – substrate combination. Many applications continue to be successful after 30 years,

whereas some 20-year-old applications have lost most of their original bond strength. As with other high-performance sealants, adhesion problems with silicone sealing materials are often caused by inadequate cleaning and joint preparation.

Most of the early silicones (and some of the present ones) show poor tear resistance, and for this reason they are not generally recommended for high-abuse areas. If a poor-tear-resistance silicone suffers a cut, the cut may propagate along the sealant bead and lead ultimately to failure. It should be noted, however, that some modern silicones have excellent tear resistance, and are used even in sidewalks. A large market for highly tear-resistant, low-modulus silicones is as highway and airport runway sealants.

5.3. Advantages, Markets, and Limitations

Silicone sealants offer the advantages of superior weatherability, great longevity, wide temperature service range, fast cure, and wide modulus range. In the construction industry, common applications are associated with insulating glass, structural glazing, pavement sealing, and perimeter weathersealing. In the home, silicones are most often used as bathtub caulks, grouts, and sink sealants because of their stability with respect to common cleansers and disinfectants as well as their longevity. In the automotive market, cure-in-place gaskets are commonly made of silicone. Many high-temperature industrial applications also specify silicones, and electronic components are often sealed with silicones. The fact that so many different types of silicones exist makes it difficult to generalize. This is particularly true because of the wide diversity of byproducts emitted when various types of silicones cure (acetic acid, amines, ketoximes, and alcohols). Each type of silicone sealant is limited by certain restrictions, and close scrutiny is required to ensure a proper choice.

In general, most contemporary silicones have the following limitations:

1) Silicone sealants are not abrasion resistant, and they must be recessed below the substrate surface to avoid abrasive contact (e.g., with vehicles in highway applications).
2) Except for specialty silicones (aquarium sealants and similar products), silicone sealants are generally not recommended for applications involving continuous water immersion because of the potential for adhesive failure.
3) Most moisture-cure silicones are not paintable. Certain silicones show improved properties in this respect, but they are still not as paintable as other elastomeric sealants.
4) While silicone sealants adhere well to most other sealants, other sealants usually do not adhere to silicones. Thus, it is generally acceptable to repair nonsilicone sealant failures with a silicone product, but usually not to repair a silicone with a nonsilicone.

5.4. Major Suppliers

The major manufacturers of silicone sealants are Dow Corning, General Electric, Wacker Silicones, Rhône-Poulenc, Bayer, and Shin-Etsu.

6. Environmental Protection

Virtually all sealants in all the generic categories release some material to the environment. However, the amount of volatiles released can vary significantly among different generic types and as a function of formulation within each type. In general, there is a trend toward replacing high-volatile formulations, such as solvent-based sealants, with more environmentally friendly sealant systems such as those that are $> 90\,\%$ solid, water-borne systems, and systems with special chemistries like the addition-curing silicones, which release little or no volatiles.

1. Introduction

A seasoning is a mixture of ingredients added to a food in order to improve its palatability and appearance.

"Seasoning" is the broadest term commonly applied in describing modifications to the flavor, appearance, or texture of foods. Its definition includes the use of spices, herbs, extracts, flavors, sweeteners, and salts, in addition to other food ingredients. By popular convention seasonings are generally understood to be dry blends, whereas wet products used for the same purposes are commonly referred to as condiments. The term seasonings is often thought of as covering two general classes of tastes: (1) sweet, typically applicable to fruit preparations and bakery goods, and characterized by the presence of sugars in addition to spices or spice extractives with sweet characteristics (e.g., anise or cinnamon), and (2) savory, which generally implies salty, and utilizes seasoning ingredients that are pungent, tangy, woody, etc. (e.g., pepper, dill, sage).

The use of seasonings predates recorded history, and their invention is a subject for archaeological speculation. Many seasonings or specific seasoning blends have regional or ethnic origins, and the cuisine of many countries and peoples is characterized by a particular type and level of seasoning, as in curries from India and chilies in Mexican cooking.

It is commonly believed that spices first came into use in Europe after the Crusades, probably to provide some preservative effect, or to disguise the flavor of spoiled or rancid meat. Scientific evidence now exists for the antibacterial effects of certain spices, and for the antioxidant effect of some herbs.

From a commercial standpoint, the market for seasonings is generally divided into two parts: (1) the retail or home-use market, in which pure spices and simple seasoning blends are sold directly to consumers for home cooking, and (2) the industrial market, where seasoning blends are carefully formulated for use in prepared foods, snacks, soups, sauces, gravy mixes, salad dressings, etc.

In the industrial market especially, seasoning blends consist of very complex mixtures of spices, herbs, and other ingredients, which might include natural and artificial flavors, dry dairy ingredients, salts, flavor enhancers, and sugars. Such seasoning blends frequently provide a flavor and appearance "signature" as typical of a specific brand as the manufacturer's logo.

2. Uses

Foods commonly seasoned in the retail marketplace are subject to the many subtleties of region and custom. However, a list of foods commonly incorporating seasonings would include:

- Meats – sausages and other cased meats, precooked and preserved (pickled, corned, or salted) products, marinades
- Salad dressings
- Snack foods – potato and corn chips, extruded snacks made from wheat and other grains, popcorn, etc.
- Soups, sauces, and gravies – wet or dry mixes
- Stuffings (bread-based preparations)
- Baked goods – pastry, cookies, frosting, biscuits, crackers

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_515

– Dips and spreads – salsa, cheese and other dairy spreads
– Pickles

3. Resources and Raw Materials

Because the term seasonings encompasses such a broad range of materials, it is difficult to enumerate all the items that might be used. Typically, seasonings would be drawn from the following groups of materials (→ Flavors and Fragrances, Chap. 3.):

– Spices – whole or ground
– Spice extracts – oleoresins or essential oils
– Salts – sodium chloride, sodium phosphates, sodium aluminum phosphates, sodium diacetate, etc.
– Sugars – sucrose, dextrose, lactose, maltose
– Flavor enhancers – monosodium glutamate (MSG), ribonucleotides
– Alliums – onion, garlic, shallots, chives
– Dairy products – cheeses, dry milk, dry whey
– Acids – acetic, lactic, citric, malic
– Roots – ginger, licorice, horseradish
– Hydrolysates – hydrolyzed vegetable protein (HVP), autolyzed yeast
– Natural and artificial flavors – smoke, meat, dairy, etc.
– Vegetable products – tomatoes, peppers, celery, etc.

Many of the ingredients used in seasoning blends are agricultural products, requiring specific environmental conditions, so the supply of these products in consistent volume and quality is a major concern. Many of the traditional businesses or "spice houses" are global in nature, with a network of joint ventures or other business arrangements designed to protect quality and supply in the source country. The source countries are commonly third-world countries, and spice houses often supply both capital and technology in an effort to improve their raw ingredient position. Until quite recently, seasoning ingredients were collected within the source country and then transported to the country of use before cleaning and processing. The current trend is to provide capital and technology for cleaning, processing, and packaging in the country of origin. Pricing and the cost of spice ingredients tend to be volatile, because supplies have historically been unpredictable due to fluctuations in weather, political stability, or the availability of labor.

4. Production

As noted previously, seasoning blends are normally dry materials, and several basic processes are important in their production.

Milling. Hard spices and herbs are commonly milled or ground to reduce the particle size as required for a specific application. For example, salad dressings might require herbs and garlic in the 2 – 4 mm size range, whereas a taco-chip seasoning would require particles sizes of < 0.1 mm. In addition to reducing the particle size, milling and grinding operations release flavoring components, and great care is exercised with regard to temperature and packaging during and after milling or grinding in order to retain volatile flavors to the greatest extent possible.

Spray Drying. Products that are liquids, pastes, or semi-solids often must be converted into dry, free-flowing powders for utilization in seasoning blends. Dairy products are typically spray dried and then introduced in the form of cheese powder, buttermilk powder, whey powder, etc. Spray drying is also useful for protecting essential oils or oleoresins in a dry form. Examples include spray-dried oil of dill, oleoresin black pepper, etc.

Dry Blending. Vertical and horizontal mixers and blenders of all types are utilized to produce seasoning blends. The principal effect is to produce a uniform blend of the various raw materials. Many seasoning components generate considerable dust, so vegetable oils are sometimes incorporated to reduce the dust level. In the case of seasoning blends that contain significant amounts of fine granular materials such as salt or sugar, liquid ingredients (e.g., extracts, oleoresins, and essential oils) can be added directly to the blend and "plated" onto the crystalline compounds. Coloring agents, such as oleoresin paprika, are frequently added to a dry blend as well, but thorough mixing and considerable care

must be invoked to produce uniform and predictable color levels.

Quality control of seasoning blend production requires special care in the following areas:

Raw Material Selection. Since seasoning blends are used to enhance flavor and appearance, the principal quality-assurance techniques involve sensory testing together with analysis of such measurable parameters as particle size, essential oil content, and microbiological levels. Trained panels and controlled standard samples are typically required to assure consistent flavor and appearance.

Formulation. Many of the basic ingredients in seasonings are raw agricultural products, with variable levels of flavor, taste, or color, so some latitude in formulation must be allowed in order to produce a consistent finished product. Where consistency of flavor and appearance is of ultimate concern, the use of isolated essential oils, oleoresins, extracts, and flavors is preferred, as these products can be standardized more easily than raw agricultural products.

Process Control. Processing usually results in elevated temperatures due to friction or heat application, and great care must be taken to protect the heat-sensitive flavoring compounds. Milling is commonly carried out under cryogenic conditions. Blending is often accompanied by cooling or other temperature-minimizing actions, and spray drying is adjusted to protect flavor yield rather than to maximize flavor impact. Relative to other food ingredients, seasonings are very expensive. Protection against flavor loss during processing and shipping is a significant economic consideration in the production process.

5. Storage and Transportation

Seasonings are dry products whose value is defined by their ability to provide flavor enhancement to food. Because flavor compounds are typically volatile and subject to change or loss in storage and transportation, temperature control and the selection of appropriate packaging is a vital concern. Seasoning blends are usually packed in multi-wall paper bags with moisture- and vapor-barrier layers. Fiber drums with plastic liners and vapor-proof lid seals are also common. A storage temperature $< 25\,^{\circ}\mathrm{C}$ is recommended, as is a relative humidity $< 70\,\%$. In warm climates transportation via refrigerated conveyance has been found to be economically justifiable as a means of preserving flavor quality.

6. Quality Specifications

Quality specifications rely heavily on sensory testing to monitor flavor quality and level. It is critical that standard samples be selected jointly by the customer and the supplier as references for use in sensory testing. Such samples are typically packaged in glass containers and held below $-10\,^{\circ}\mathrm{C}$ to minimize flavor change over time. Standard samples must be renewed from time to time by mutual agreement.

Special sensory panels must be selected and trained for evaluating various control parameters. Color control is maintained by the use of tristimulus colorimeters (ASTM E 1347-90, D 2244, E 308; DIN-5033). Typical analytical determinations usually involve salt and sugar. Microbiological analysis is directed toward total plate count, yeast and mold, *Escherichia coli*, and *Salmonella*. Particle-size determinations are also important, with the most common methods based on standard sieve analysis.

7. Economic Aspects

Because the definition of seasonings is so broad, no reliable production or consumption data exist. However, it has been estimated that the average person consumes on the order of $1-2$ kg of seasonings per year, excluding salt. Published figures in the 1990s suggest a total annual consumption in the United States of 3.5×10^5 t; a corresponding figure for Japan is 1×10^5 t.

The list of producers of industrial seasoning blends is long: the United States alone has over 45 major producers, including Borden, Durkee-French, General Spice, Givaudan, Heller Seasonings & Ingredients, Kikkoman, Kraft Food Ingredients, McCormick, Quest International, Spice Islands, and Universal Foods, to name

but a few. Important producers elsewhere in the world include Fuchs, Haarmann & Reimer, and Maizena (Germany); Unilever (Netherlands); Buitoni Perugina and Findus (Italy); Ajinomoto, Itoham Food, Kikkoman Shoyu, and Takeda (Japan); Dragoco, Firmenich, and Nestlé (Switzerland); and Reckitt & Colman, H. E. Daniel, Soutra Foods, and Spicehampton (United Kingdom). McCormick is also represented by a number of international production divisions.

1. Introduction

Fabled that the halcyon broods upon her nest floating on the calm sea in the halcyon days.

Halcyon (αλκυων = kingfisher), a bird of which the ancients fabled to breed about the time of the winter solstice in a nest floating on the sea, and that it charmed the wind and waves so that the sea was specially calm during the period [6].

Sedative drugs are used in clinical situations where the induction of a sleepy, calm, tranquil state is the objective of therapy. For example, the sedative and anxiolytic properties of these drugs may be used to moderate excitement and calm the frightened patient who is anticipating surgery. Preanesthetic sedation may even permit a reduction in the administered dose of the general anesthetic and may shorten the time required for recovery from general anesthesia. The ideal agent for conscious sedation should allay anxiety, produce antegrade amnesia, have a rapid onset of action, and a duration of action short enough to permit a rapid recovery. Its dose – response relationship should be well defined and predictable with a broad therapeutic ratio regarding respiratory and cardiovascular safety. Drugs for intravenous or intramuscular administration should be water soluble and should not produce venous irritation or pain at the injection site [1–5].

There are several reasons for administering sedative drugs before the induction of general anesthesia. A primary goal is to reduce anxiety without producing excessive sedation. Sedated patients with cardiovascular disease are less likely to suffer postoperative complications related to myocardial ischemia and large fluctuations in blood pressure. Also, reduction of anxiety may make the patient more cooperative. Probably because so many factors influence postoperative recovery, there may not be a consistent relationship between relief of anxiety and benefit to postoperative recovery; nevertheless, relief of anxiety is humane and should be attempted for every patient [7].

Another goal of preanesthetic sedation is the induction of amnesia for the surgical procedure. Antegrade amnesia for brief procedures, such as endoscopy, is desirable and prepares the patient to accept repeated examinations [8], [9]. However, the induction of amnesia by drugs used for preanesthetic sedation can be a problem, especially in ambulatory patients [7]. The frequency of occurrence of amnesia in postsurgical patients is directly related to the administered dose of drugs, such as the benzodiazepines. Amnesia may be observed occasionally when sedative doses of benzodiazepines are used alone. It may, however, also occur in the majority of patients who receive benzodiazepines in combination with other drugs that can be used as preanesthetic adjuncts such as the anticholinergic agent, scopolamine, or meperidine (pethidine), an analgesic agent with anticholinergic properties.

2. Rationale for the Selection of Individual Agents

2.1. Therapeutic Spectrum of Action and Requirements

Since sedation may be achieved by drugs belonging to diverse chemical classes that work by different pharmacological mechanisms, the sedatives are not a sharply defined group of drugs. The choice of the individual drug depends upon its therapeutic spectrum and the clinical situation in which it is to be used. This review is restricted to drugs used for preanesthetic sedation and does not include agents that are used to relieve preoperative pain with or without the induction of accompanying sedation. Various drugs, including the barbiturates, phenothiazines, butyrophenones [10], and the narcotic analgesics, have been used for the relief of anxiety and for their sedative effects prior to surgery but, they have been supplanted largely by the benzodiazepines [1–5], [7]. The preanesthetic use of narcotic analgesics is limited principally to relief of preoperative pain, to ameliorate pain associated with regional anesthesia, and for attenuation of the cardiovascular response to endotracheal intubation [7]. Certain neuroleptics such as the phenothiazine, chlorpromazine; the butyrophenones, haloperidol or droperidol; and the analgesics, fentanyl, alfentanil, or sufentanil are used often as general anesthetic adjuncts. For example, potent analgesics are used in combination with small doses of neuroleptics to induce neuroleptanalgesia. Preanesthetic use of individual neuroleptic or analgesic drugs is not discussed herein; this subject has been adequately covered elsewhere (→ Anesthetics, General).

2.2. Mechanism of Action

Benzodiazepines and barbiturates modulate the affinity of the oligomeric receptor for the inhibitory neurotransmitter, γ-aminobutyric acid (GABA). Enhanced GABA binding results in an increase in intraneuronal chloride ion concentration with reduced neuronal excitability. Sedative doses of the benzodiazepines inhibit neuronal transmission within forebrain limbic regions but higher doses also depress brainstem loci that modulate skeletal muscle tone. The barbiturates directly depress the sensory and motor cerebral cortex and reduce the excitability of the reticular activating system (RAS). See also → Neuropharmacology, Chap. 3.2.3., → Neuropharmacology, Chap. 3.2.4. The phenothiazines and butyrophenones block receptors for dopamine. This results in a reduction of afferent transmission to the brainstem RAS by inhibition of a parallel system. The sites of the sedative action of the antihistamines and the opioids are unclear and are probably diffuse. The euphoriant actions of the opioids probably involve hypothalamo – cortico – limbic structures while their analgesic effects are localized within brainstem nuclei which inhibit nociceptive afferent input.

3. Individual Agents

3.1. Benzodiazepines

Benzodiazepines possess a wider therapeutic margin of safety than other agents and are used worldwide for preanesthetic sedation. The range of doses for their sedative and hypnotic effects is broad. The range of doses in the following paragraphs have been recommended for adults, doses for children should be lower. Compared to the barbiturates, the benzodiazepines are safer with regard to their effects on cardiovascular and respiratory function. However, caution should be exercised in the elderly, in patients with chronic liver disease, or when they are used in combination with other CNS depressant agents. In addition, the benzodiazepines have been developed for use as psychopharmacological agents (→ Psychopharmacological Agents, Chap. 4.1.), anticonvulsant agents (→ Antiepileptics, Chap. 2.6.), hypnotics (→ Hypnotics, Chap. 5.4.), and skeletal muscle relaxants (→ Skeletal Muscle Relaxants).

Diazepam [*439-14-5*] has been in use as an intravenous sedative since the early 1960s.

It is very effective for the relief of anxiety before surgery. Its primary use is for oral premedication in doses of 5 – 15 mg. Although it has a very rapid onset of action when administered parenterally (intravenously or intramuscularly), its anxiolytic and sedative effects do not onset until 1 h after oral administration. It is effective for several hours and, as with other benzodiazepines, its elimination half-life is increased in the elderly. Diazepam is metabolized to desmethyldiazepam which is pharmacologically active. Formerly, diazepam was administered extensively in intravenous doses of 0.1 – 0.3 mg/kg. Its use by this route has declined because the injectable formulation contains propylene glycol which may produce venous thrombosis, local irritation, swelling, and vascular impairment. Because of the possibility of precipitation in the infusion fluid, diazepam injection should not be diluted and administered as an intravenous infusion. Also, it is unstable in poly(vinyl chloride) infusion containers and tubing. Diazepam is effective when doses of 0.1 – 0.3 mg/kg are administered intramuscularly but its effects are not as reliable by this route. It is commercially available as tablets, sustained-release capsules, oral solutions, oral drops, and an injectable solution.

Trade Names. Diazepam (various manufacturers); Diazepam Oral Solution, Diazepam Intensol (Roxane); Valium, Valrelease (Roche); Zetran (Hauck).

Lorazepam [*846-49-1*] is a benzodiazepine with greater sedative and amnestic activity and potency than diazepam.

Sedation can be obtained in most adults after administration of 0.044 mg/kg intravenously or 0.05 mg/kg intramuscularly. The injectable product is formulated with a mixture of poly(ethylene glycol) 400 and propylene glycol and is tolerated better than diazepam when administered intravenously. Even when injected, the onset of action of lorazepam may be delayed for up to 40 min. The duration of its sedative and amnestic action may, however, be three to four times that of diazepam. Lorazepam is metabolized to a biologically inactive product by conjugation with glucuronic acid.

Trade Name. Atavan (Wyeth-Ayerst).

Triazolam [*28911-01-5*] is a benzodiazepine that is primarily used as a sleep-inducing hypnotic agent rather than as an anxiolytic.

Triazolam has sedative activity and is typically administered orally (0.125 – 0.25 mg), however, up to 0.5 mg may be administered for sleep induction. Anesthetic requirements may be considerably reduced because of its high degree of efficacy as a CNS depressant. Since triazolam has a relatively short half-life (1.5 – 3 h), it may be administered for preoperative sedation when a short-acting agent is desired. Peak plasma levels are obtained within 2 h. It is metabolized to a biologically active α-hydroxylated product. Benzodiazepines with short half-lifes generally do not have residual effects; nevertheless, the patient should be held in the recovery room until locomotor ataxia or amnestic effects have abated.

Trade Name. Halcion (Upjohn).

Midazolam [*59467-70-8*]. The hydrochloride is a water-soluble, benzodiazepine CNS depressant that is formulated for intravenous or intramuscular administration.

It does not produce venous irritation when injected. It has a more rapid onset of action, shorter duration of action, higher potency, and more

rapid elimination half-life than other benzodiazepines. When used for conscious sedation, its CNS effects are dependent upon the dose and route of administration. Midazolam has anxiolytic activity and is capable of inducing amnesia for the surgical procedure in most patients. It is metabolized to 1-hydroxymethylmidazolam, which is then conjugated with glucuronic acid; both steps proceed rapidly. Its onset of action occurs approximately 15 min after intramuscular administration and recovery may be complete within 2 h. Since intravenous administration has been associated with respiratory depression and arrest, dosage should be individualized, especially for the elderly. One way to accomplish this is by administering the drug slowly over at least 2 min or until the patient's speech becomes slurred. This effect may be accomplished with as little as 1 mg. The maximum intravenous or intramuscular dose per patient is 5 mg.

Trade Name. Versed (Roche).

3.2. Barbituric Acids

The barbiturates such as pentobarbital, secobarbital, and phenobarbital produce sedation at doses that are lower than their hypnotic doses. See also →Hypnotics, Chap. 5.1. However, these agents are used only occasionally as sedatives because they may have a narrow therapeutic window, i.e., they can produce respiratory and cardiovascular depression when administered at relatively small multiples of their sedative or hypnotic doses. Tolerance to the sedative effects of these agents develops rapidly when they are administered repeatedly. Therefore, tolerance may be observed in patients who have been taking barbiturates, alcohol, or other CNS depressant drugs. Barbiturates are metabolized primarily by the hepatic microsomal enzyme system and induction of this system contributes to the development of tolerance. Barbiturates should not be given to patients who are experiencing pain because they may cause disorientation rather than sedation. Their use for preanesthetic sedation has been largely supplanted by the benzodiazepines.

Pentobarbital [*76-74-4*] is a short-acting barbiturate for preanesthetic sedation that may be administered orally or by deep intramuscular injection.

No more than 5 mL should be injected into a single intramuscular site because of its tissueirritating properties. Doses are calculated on the basis of the patient's age, weight, and physical condition. Cardiovascular or respiratory depression is minimal at sedative doses. Pentobarbital solution is strongly basic so its intravenous use should be restricted to conditions in which other routes of administration are not feasible as media with high pH values injure the lining of the vein. When intravenous administration is imperative because prompt sedation is required, the rate of administration should not exceed 50 mg/min.

Trade Names. Nembutal, Nembutal Sodium (Abbott).

Secobarbital (sodium salt) [*309-43-3*] is a short-acting barbiturate for preanesthetic sedation that may be administered orally or by deep intramuscular injection.

No more than 5 mL should be injected into a single intramuscular site because of its tissue-irritating properties. Doses are calculated on the basis of the patient's age, weight, and physical condition. Cardiovascular or respiratory depression is minimal at sedative doses. Since secobarbital sodium solution is strongly basic, its intravenous use should be restricted to conditions in which other routes of administration are not feasible. When intravenous administration is imperative because prompt sedation is required, the rate of administration should not exceed 50 mg/15 s. Secobarbital sodium injectable solution is formulated with 50 % poly(ethylene glycol) and 0.25 % phenol.

Trade Name. Seconal Sodium (Lilly).

Phenobarbital [*50-06-6*] is a long-acting barbiturate for preanesthetic sedation that may be administered orally or by deep intramuscular injection into a large muscle.

Care must be taken to avoid injecting solutions into or near peripheral nerves or arteries because of the possibility of permanent tissue damage. Doses are calculated on the basis of the patient's age, weight, and physical condition. Luminal sodium injectable solution is formulated with 10 % alcohol and 67.8 % propylene glycol.

Trade Names. Barbita (Vortech), Luminal Sodium (Winthrop-Breon), Solfoton (Poythress).

3.3. Antihistamines

Histamine-blocking activity was first detected in1937in one of aseries of amines with aphenolic ether function synthesized by FOURNEAU. This compound was found to be useful in treating anaphylactic shock and some derivatives were found to possess highly potent and clinically useful antihistaminic activity. Since many antihistaminic drugs (→ Antiallergic Agents, Chap. 2.) also have anticholinergic and sedative effects, they have been found to be effective general anesthetic adjuncts. When used for preanesthetic sedation, the range of doses mentioned in the following paragraphs are recommended for adults. Doses for children should be lower.

Hydroxyzine [*68-88-2*] is a sedative piperazine antihistamine with anxiolytic, antiemetic, antisecretory, and bronchodilator effects.

Hydroxyzine hydrochloride is administered orally in a dose range of 50 – 100 mg for preanesthetic sedation; however, it is more commonly administered intramuscularly in a dose range of 25 – 100 mg. While this drug potentiates other CNS depressants and lowers the required amount of the general anesthetic, it does not prolong anesthesia. Sedative doses have minimal effects on respiration or cardiovascular function.

Trade Names. Atarax (Roerig), Vistaril (Roerig-Pfizer).

Diphenhydramine [*58-73-1*] is a sedative antihistamine belonging to the ethanolamine class.

It also has antiemetic and antiparkinson effects. It may be administered intravenously or intramuscularly in a dose range of 10 – 50 mg for preanesthetic sedation.

Trade Name. Benadryl (Parke-Davis).

Promethazine [*60-87-7*] is a phenothiazine and has a long history of use.

It was introduced in 1946 for use in allergic conditions and has been used as a preanesthetic medication for its sedative and antiemetic effects. Promethazine hydrochloride [*58-33-3*] may be administered orally in a dose range of 25 – 50 mg. The preferred parenteral route is by deep intramuscular injection at a similar dose. The duration of action of promethazine is 4 – 6 h.

Trade Name. Phenergan (Wyeth-Ayerst).

Propiomazine [*362-29-8*] is a phenothiazine that is a short-acting sedative, antiemetic, antihistamine.

Propiomazine hydrochloride may be administered by the intravenous or intramuscular route in a dose of 20 – 40 mg.

Trade Name. Largon (Wyeth-Ayerst).

1. Introduction

Selenium [*7782-49-2*], atomic number 34, A_r 78.96, is a member of group 16 of the periodic table and thus belongs to the chalcogens. Consonant with its position between the nonmetal sulfur and the metalloid tellurium, it has mainly nonmetallic properties.

Naturally occurring selenium consists of six stable isotopes: ^{74}Se (0.9 %), ^{76}Se (9.0 %), ^{77}Se (7.6 %), ^{78}Se (23.5 %), ^{80}Se (49.8 %), and ^{82}Se (9.2 %). Selenium is 66th in order of natural abundance in the earth's crust, with an average concentration of 0.05 ppm.

Selenium was discovered in 1817 by BERZELIUS in deposits in lead chambers used for the production of sulfuric acid from copper pyrites. The name selenium is derived from the Greek word for moon and reflects the close resemblance between selenium and tellurium (= earth), which was discovered about 20 years earlier.

Selenium is a byproduct of the extraction of metals such as copper, zinc, and lead, and has many industrial applications based on its chemical and physical properties. Its semiconducting properties and the light-induced variation of its electrical conductivity are of particular importance.

2. Properties [1–4]

Like sulfur, selenium exists in several allotropic forms. The structures of these and the mechanism of transformation of one into another are not completely understood. Red selenium is a thermodynamically unstable, high-energy modification produced by precipitation at low temperature, crystallization of selenium from solution, or quenching of selenium vapor or molten selenium. The three modifications of monoclinic selenium (α-, β-, and γ-selenium) consist of Se_8 rings and differ only in the packing of these in the crystal (Fig. 1). The red, amorphous form consists of chains in an irregular arrangement. It is soluble in carbon disulfide and to some extent in benzene, giving red solutions from which it can be crystallized. Red selenium is an electrical nonconductor. In the vapor phase, selenium exists mainly as Se_8 rings. At higher temperature these decompose into smaller units, eventually forming Se_2 molecules.

Thermodynamically unstable vitreous or amorphous forms are obtained by rapid cooling of molten selenium. The structure of these modifications is not yet fully understood. Presumably, high molecular mass selenium rings of various sizes are present, which explains the poorly defined melting point of industrial-grade vitreous selenium. This product softens at ca. 50 °C to a rubberlike state and is transformed at > 100 °C into the gray, crystalline form, with release of the heat of crystallization. The black, nonconducting form is slightly soluble in carbon disulfide. Structures similar to those in vitreous selenium are present in molten selenium.

On heating to > 100 °C, both the red and the black forms are transformed into the stable, gray, hexagonal ("metallic") form in an exothermic reaction. This modification is also produced by reducing selenous acid with sulfur dioxide at high temperature. Unlike the ring structure of the unstable forms, it consists of helical chains

10.1002/14356007.a23_525

in which the structure is repeated at every third atom (Fig. 1). Gray selenium is a semiconductor whose electrical conductivity increases by a factor > 1000 under the influence of light (photoconductivity).

Figure 1. Structures of selenium
a) Se_8 molecule in red α-, β-, and γ-selenium; b) Helical chains in hexagonal gray selenium [4]

Impurities have a great influence on crystallizing properties, so results given in earlier research work, where impurity content is not quoted, are often erroneous. Also, the previous history of the material (e.g., high-temperature treatment) plays an important role in the transformations between various allotropic forms. The thermal properties of selenium can be conveniently investigated by differential thermal analysis [8]. Figure 2 shows the various transformations of distilled selenium on melting. The brittle vitreous form is transformed at 50 °C into the ductile vitreous form (glass transition). Above ca. 120 °C, vitreous selenium changes into the stable hexagonal crystalline form, which melts at 220 °C.

Important physical properties of selenium are given below [1,4]:

Atomic number	34
Electronic structure	$[A_r]3d^{10}4s^24p^4$
Relative atomic mass	78.96
Oxidation states	−II,0,+IV,+VI
Atomic radius, nm	0.140
Ionic radii, nm	
Se^{2-}	0.191
Se^{4+}	0.050
Se^{6+}	0.042
Ionization energy, kJ/mol	940
Ionization potential, eV	
I	9.75
II	21.5
Electronegativity (Pauling)	2.4
Density at 25 °C, g/cm^3	
Hexagonal	4.189
α-Monoclinic	4.389
Vitreous	4.285
Liquid (490 K)	3.975
Melting point, °C	217
Boiling point, °C (101.3 kPa; 760 mm Hg)	684.7 (±0.03)
Vapor pressure, kPa	
344.6 °C	0.133 (1 mm Hg)
431.5 °C	1.333 (10 mm Hg)
547.4 °C	13.33 (100 mm Hg)
636.5 °C	53.32 (400 mm Hg)
Electrical resistivity, Ω/cm∗	
25 °C	10^{10}
400 °C	1.3×10^5
Glass transition temperature, °C (vitreous modification)	30.2∗∗

∗ Strongly dependent on purity and light intensity.
∗∗ Strongly dependent on purity.

The electrical conductivity is strongly dependent on purity. Thus, the conductivity of selenium, including the poorly conducting amorphous form, can be increased considerably by traces (a few parts per million) of halide ions or by alloying elements such as tellurium or arsenic. Because the electrical properties are sensitive to the presence of crystal defects, the purity of selenium, which can be deliberately controlled by doping or alloying with other elements, plays an important role in its use in electrical and electronic applications.

The chemical properties of selenium are intermediate between those of sulfur and those of the metalloid tellurium. In its compounds, it mainly exhibits the oxidation states −II, +IV, and +VI. The oxidation state +VI is considerably less stable than for sulfur, and in acid solutions is attained only by the action of strong

Figure 2. Differential thermal analysis of distilled high-purity selenium after 3 h at 450 °C to give a material of uniform structure [8]

oxidizing agents such as chlorine or hydrogen peroxide. Selenate(VI) is more easily obtained by oxidation in alkaline solution. The redox potentials of selenium in acid and alkaline solution are as follows [4, 7]:

Oxidation State	−II		0		
Acid	H_2Se	$\xrightarrow{-0.40\ V}$	Se	$\xrightarrow{+0.74\ V}$	
	+IV		+VI		
	H_2Se	$\xrightarrow{+1.15\ V}$	SeO_4^{2-}		

	−II		0		
Alkaline	Se^{2-}	$\xrightarrow{-0.92\ V}$	Se	$\xrightarrow{-0.37\ V}$	
	+IV		+VI		
	SeO_3^{2-}	$\xrightarrow{+0.05\ V}$	Se^{2-}		

Selenium burns in air to form selenium dioxide, which has the smell of rotten radishes. Selenium is oxidized by nitric acid to selenous acid. No reaction occurs with nonoxidizing acids such as hydrochloric acid. Hot, concentrated sulfuric acid dissolves selenium, giving a green color and forming polymeric selenium cations, for example:

$$Se_8 + 3\,H_2SO_4 \longrightarrow Se_8^{2+} + 2\,HSO_4^- + SO_2 + 2\,H_2O$$

With chlorine, vigorous oxidation to selenium tetrachloride occurs. Selenium reacts with electropositive elements (e.g., many metals) to form selenides and is therefore strongly corrosive, especially at high temperature. With hydrogen, the toxic gas hydrogen selenide is formed. Selenium combines with sulfur to form nonstoichiometric alloys.

Selenium dissolves in solutions of strong alkali, disproportionating into selenide and selenite. It dissolves in alkali-metal sulfides, sulfites, and cyanides, with formation of addition compounds.

3. Occurrence and Raw Materials

Pure selenium minerals are very rare. Thus, berzelianite (Cu_2Se), tiemannite (HgS), and naumannite (Ag_2Se) are never processed simply to obtain selenium. However, selenium occurs in various concentrations as an accompanying element in many sulfidic ores, although isomorphic substitution in copper pyrites, iron pyrites, or zinc blende cannot exceed a theoretical maximum of 0.5 % because of the larger ionic radius of selenium (Se^{2-}: 0.191 nm, S^{2-}: 0.174 nm). The selenium content of pyrites, zinc blende, galena, and molybdenite is too low for economic recovery. However, most copper concentrates from ore flotation contain ca. 100 – 400 g/t selenium and are hence the most important sources of selenium. Selenium production is therefore closely linked to copper production.

Selenium occurs in low concentrations (ca. 1 – 5 g/t) in some types of coal and mineral oil.

In addition to extraction of selenium from copper ore, the recycling of photocopying drums and rectifiers is becoming an important source.

4. Production

4.1. Primary Production

Selenium is an accompanying element obtained during copper production (→ Copper). The sulfidic copper concentrate (e.g., chalcopyrite) is smelted in an oxidizing atmosphere to give a copper matte containing 40 – 70 % Cu. This is then blown in a converter to yield crude copper. After reduction of excess copper oxide, the crude copper is cast into anodes. Along with other impurities, these copper anodes contain 25 – 70 % of the selenium, depending on the smelting process. The rest of the selenium vaporizes during smelting, mainly as selenium dioxide. This is reduced to the element by the sulfur dioxide produced during smelting and collects in the slime formed in the gas purification equipment. However, recovery is generally uneconomical due to the complex composition of the slime. Likewise, in the roasting of pyrites and zinc or lead ore, most of the selenium volatilizes and concentrates in the slime in the gas purification equipment.

The selenium remaining in the copper anodes is mainly in the form of Cu_2Se, or sometimes CuAgSe and Ag_2Se, depending on the silver content. Because they are insoluble in the sulfuric acid electrolyte, these selenides remain in the anode slime during electrolytic refining of the copper, as do the noble metals. As a result of the high stability of noble-metal selenides, the copper selenides initially present in the anodes can be converted to silver selenide or gold selenide under the influence of the electrolyte, depending on the noble-metal content. The selenium in the anode slime is therefore in the form of various compounds, depending on the silver content. The selenium content of the anode slime varies with the raw material and can reach > 20 %.

Selenium contents (%) of anode slimes (from which residual copper has not been removed) from various copper tankhouses are as follows [9]:

CCR (Noranda), Canada	10.0
Chuquicamata, Chile	4,0
Copper Refineries Pty, Australia	0.7
IMI Refiners, United Kingdom	2.0
Inco, Canada	8.4
Kidd Creek, Canada	19.5
MHO, Belgium	5.1
Norddeutsche Affinerie, Germany	7.5
Palabora, South Africa	3.6
Phelps Dodge, United States	8.8
Southwire, United States	0.6

The precious metals can be recovered only by decomposing the very stable selenides with very strong acid or alkali, or by roasting. Selenium must be removed from the anode slime before the noble metals can be recovered. The important processes are [10]:

1) Fusion with sodium carbonate
2) Roasting with sodium carbonate
3) Direct oxidation (roasting)
4) Oxidative leaching with sodium hydroxide solution under pressure
5) Roasting with concentrated sulfuric acid
6) A hydrometallurgical process of chlorination in hydrochloric acid

In roasting with sodium carbonate, the anode slime is first treated with sulfuric acid solution to remove the copper and then mixed with sodium carbonate and water to give a stiff paste. The paste is extruded or pelletized, and dried. It is then roasted at 530 – 650 °C in a stream of oxygen – air. Sodium carbonate prevents vaporization of the selenium as selenium dioxide by converting it completely into sodium selenate. The roasted pellets are ground and leached with water to dissolve sodium selenate. The precious metals remain in the solid residue, which also contains tellurium in the form of sodium tellurate if higher roasting temperatures are used. The selenate is crystallized from solution and reduced with active carbon to sodium selenide, which is redissolved in water and oxidized with air to elemental selenium. However, this process leads to the formation of large amounts of wastewater.

Elemental selenium can also be precipitated from selenate solution by strongly acidifying with hydrochloric acid and reducing with iron(II) salts or sulfur dioxide. Alternatively, the sodium carbonate solution can be decomposed by adding acid to precipitate impurities such as tellurium. After filtration and further acidification,selenium is precipitated by reduction (Fig. 3).

In the direct oxidation process, copper is removed first from the anode slime by sulfuric acid. The slime is then dried and mixed with inert materials that prevent sintering, and the sele-

nium is volatilized as selenium dioxide vapor at 600 – 900 °C. Silver selenite is formed initially at < 400 °C

Figure 3. Recovery of selenium from copper anode slime by roasting with sodium carbonate

$$Ag_2Se + 1.5\,O_2 \longrightarrow Ag_2SeO_3$$

and decomposes at higher temperature

$$Ag_2SeO_3 \longrightarrow 2\,Ag + SeO_2 + 0.5\,O_2$$

Selenium dioxide and some of the sulfur dioxide formed from the sulfate fraction of the anode slime are removed from the gas phase by scrubbing with water or sodium hydroxide solution. After acidifying the wash liquor, the selenium is reduced with sulfur dioxide (Fig. 4). Very high volatilization rates are achieved at < 600 °C if the oxidative roasting is carried out in the presence of sulfur dioxide. The reaction is believed to occur via the intermediate formation of sulfur trioxide, which reacts with silver selenite:

Figure 4. Recovery of selenium from copper anode slime by acidic roasting

$$Ag_2SeO_3 + SO_3 \longrightarrow Ag_2SO_4 + SeO_2$$

This method is used by Outokumpu [11]. The selenium dioxide produced is absorbed in dilute sulfuric acid and immediately precipitated as elemental selenium by the excess sulfur dioxide in the scrubbing equipment.

Whereas roasting is carried out below the melting point of the anode slime, in the classical Doré process (Fig. 5) the anode slime is melted after addition of fluxes. A matte consisting mainly of silver selenide and a high-lead slag containing precious metals are formed. The slag can be processed in a lead smelting works, or the noble metals can be recovered by flotation.

The selenium-containing matte is oxidized in the molten state in a second stage, and selenium is vaporized as its dioxide and absorbed in a scrubbing stage. In a process operated by the Canadian copper producer Noranda, these two stages are carried out in succession in a top blown rotary converter (TBRC) [12].

Figure 5. Recovery of selenium from copper anode slime by the Doré process

Alternatively, roasting with sulfation is carried out in the presence of concentrated sulfuric acid at 500 – 600 °C after removal of tellurium [9], although the large quantities of sulfur dioxide and sulfur trioxide aerosols formed can present environmental problems, and the severely corrosive properties of sulfuric acid at high temperature are difficult to deal with.

Apart from the widely used high-temperature processes, hydrometallurgical extraction of selenium from copper anode slimes is of some importance in small plants [13–15]. For example, in the copper refinery Austria-Metall [14], the anode slime is leached with hydrochloric acid and chlorine, whereby the gold, platinum metals, and selenium (as selenous acid) dissolve, and silver remains in the residue as silver chloride. Selenium is then precipitated from the hydrochloric acid solution by reduction with SO_2.

4.2. Secondary Production

Although most selenium comes from primary production, recycling of the selenium in used rectifiers and photocopying drums is becoming increasingly important for environmental reasons. An older recovery process involves fusion with sodium hydroxide to dissolve the selenium, forming polyselenides:

$$6\,NaOH + (2x+1)\,Se \longrightarrow 2\,Na_2Se_x + Na_2SeO_3 + 3\,H_2O$$

Selenium is obtained by acidifying the solution, but toxic hydrogen selenide may be formed. This can be prevented if an alkaline solution of sodium sulfite is used in the treatment process. This dissolves selenium selectively, forming sodium selenosulfate:

$$Na_2SO_3 + Se \longrightarrow Na_2SeSO_3$$

Selenium can be recovered by acidification, which produces SO_2.

In another process, selenium is treated with sodium hydroxide solution and hydrogen peroxide to give a mixture of sodium selenite and sodium selenate. The solution is acidified, and selenium is precipitated by sulfur dioxide [16].

Selenium can also be removed mechanically from photocopying drums by using a water jet. The aluminum drum can be reused whether selenium is removed chemically or mechanically; the selenium on photocopying drums is thus 100 % recyclable without any deterioration of its quality. Recycling of photocopying drums is performed on a large scale (e.g., by the company Retorte).

Selenium can be dissolved selectively from residues by leaching with ammonia or amines in an aprotic solvent in the presence of carbon monoxide, to form amine salts of selenocarbamic acid. It can then be precipitated in a pure state by heating, with recovery of carbon monoxide and the amine [17].

4.3. Refining [3]

The roasting processes, followed by precipitation with sulfur dioxide, gives selenium with a purity usually exceeding 99 %, which is adequate for many chemical applications. However, for electronic applications or xerography, selenium must be purified further, because of the sensitivity of its physical properties to the presence of impurities.

The simplest method of purification is distillation at atmospheric pressure and ca. 650 °C, which gives a purity up to 99.99 %. All the nonvolatile elements, such as copper, nickel, iron, and tellurium (if present as the dioxide), remain in the distillation vessel. However, sulfur and mercury (as HgSe) also distill over and are thus not removed. Therefore, the crude selenium should not contain mercury. A sufficiently pure product is obtained if some of the selenium is not distilled, ca. 50 % being left behind in the distillation vessel to be returned later to the recovery process. The corrosive properties of selenium vapor cause problems during distillation, and purified selenium that is collected in cast iron vessels sometimes becomes contaminated with iron. Improved separation is obtained by vacuum distillation at 0.7 – 1.3 kPa and 360 – 400 °C, or at 0.1 Pa and 260 °C, which also reduces corrosivity [18]. A further improvement in quality is obtained if the melt is selectively oxidized by atmospheric oxygen before distillation. This gives better separation of the more readily oxidized impurities.

An alternative to distillation for producing high-quality selenium is vaporization with oxidation, the selenium dioxide vapor formed being absorbed in pure water. Mercury can be removed from the solution by adsorption, and the other metallic ions by ion exchangers. Elemental selenium is then precipitated with high-purity sulfur dioxide. Purities > 99.99 % can be achieved in this way [19]. After precipitation, the selenium powder is washed and can be remelted if desired (e.g., to produce granules or to homogenize the structure).

High-purity selenium is also obtained by the hydride process. Impure selenium is treated with hydrogen at ca. 550 – 685 °C to form hydrogen selenide, which is then decomposed at 1000 °C. Alternatively, it can be cooled to remove gaseous impurities before thermal decomposition is carried out [20].

5. Environmental Protection

Selenium is toxic at high concentration and must therefore be effectively removed from off-gases and wastewater. Since oxidizing processes are used, selenium is present in the off-gas as selenium dioxide. After cooling, it can be removed either by dust filters or, because of its high solubility, by absorption in water or sodium hydroxide solution in gas-scrubbing equipment. Because selenium dioxide is readily reduced by organic compounds or sulfur dioxide, the off-gas always contains a small amount of elemental selenium. The selenium-containing dust filtered out thus generally has a reddish color.

The wastewater treatment process and the minimum attainable selenium content both depend on the form in which selenium is present and on the other components in the wastewater. Although selenites in acid solution are reduced readily to insoluble selenium, complete removal is often difficult, because the selenium sometimes precipitates as a colloid and the reduction is very slow, especially in dilute solution. Therefore, precipitation aids such as hydroxides of aluminum or iron must be added usually. Adsorptive precipitation then enables a final content of <10 mg/L Se to be achieved in the wastewater.

Selenium-containing wastewater, as produced in the sour waters from petroleum refining, can be purified by ion exchange [21].

6. Uses [5,6]

The uses of selenium and selenium compounds can be divided into the following categories [22]:

Electronic applications	ca. 25 %
Pigments	ca. 10 %
Glass	ca. 40 %
Metallurgy	ca. 10 %
Agricultural and biological applications	5 %
Other uses (e.g., additives for rubber vulcanization, oxidation catalysts)	ca. 10 %

Rectifiers. Selenium conducts electricity preferentially in one direction, and this property has been utilized since 1920 for converting alternating to direct current. A selenium rectifier consists of a steel or aluminum plate coated with nickel, with an additional coating of selenium, 50 – 60 µm thick. A sprayed cadmium alloy is used as a counterelectrode. Several of these rectifiers can be stacked in series. The efficiency of rectification is ca. 85 %. Although selenium rectifiers have been increasingly replaced by germanium and silicon diode rectifiers, selenium is still used where the performance of the rectifier

must be maintained even in the presence of high countervoltage peaks.

Xerography (→ Imaging Technology , Chap. 2.1.1.) [23]. The use of selenium in photocopying technology is based on its sensitivity to light. Selenium, which may be highly pure, doped, or alloyed, is deposited by a vaporization process to form a film, ca. 50 µm thick, on an aluminum drum. In the copying process, the selenium surface is first charged by a high-voltage corona discharge. The drum is then exposed to the projected light from the picture. Where the light falls on the drum, the charge on the selenium flows away, and a latent picture is thereby formed. After the illumination stage, the thermoplastic toner powder is applied to the drum, attracted electrostatically to the charged parts (not illuminated), and then fixed by heat. A photograph of a used photocopier drum after 60 000 photocopying runs is shown in Figure 6. The pure, amorphous selenium originally used to coat the drums is very fragile and crystallizes at high temperature. Therefore, selenium stabilized with tellurium or arsenic is now often used (selenium – tellurium alloys or arsenic triselenide), generally doped with small amounts of chlorine. The alloys containing high-purity tellurium enable copying rates to be increased and light of a wider spectral range to be used. A still-higher copying rate and wider spectral range are possible with arsenic triselenide, which has been used increasingly despite its toxicity and problems in manufacture. The drums also have a considerably longer life. The selenium-based system is now being replaced by organic photoconductors and amorphous silicon in low-cost applications. However, selenium is maintaining its position in industrial applications because of its long life and high photocopying capacity. Whereas a drum with organic photoconductors has a lifetime of ca. 10 000 – 30 000 copies, drums coated with selenium can withstand more than 100 000 copying operations.

A potential application of xerography with selenium as the photoconductor is in medicine. Here, X-rays are used instead of visible light to form the latent image. The advantage of this process lies in the possibility for direct digitization without producing a copy or a film, so that the X-ray image is generated directly by a computer on a visual display unit, and can be stored and processed. Although several patents exist and comprehensive research has been carried out, the process is not yet in general use [24, 25].

Figure 6. Selenium-coated photocopier drums after 60 000 copies

Glass Manufacture. Selenium and selenium compounds are used in silicate glass both in decolorization and as a colorant for producing intense yellow to red glass for special applications (selenium pink glass).

The main application in glass manufacture is in the decolorization of glass, which is always colored green to yellow green by traces of iron(II) and iron(III). The addition of 30 – 150 g/t selenium compensates for this color by adding the pink of the selenium, with no apparent reduction in transparency [26]. Formerly, selenium was added mainly as the element. However, elemental selenium volatilizes below the melting temperature of glass, so the yields were usually $< 50\,\%$. Therefore, selenium compounds such as sodium selenite, sodium selenate, barium selenite, or zinc selenite are now increasingly used. Even so, some volatilization losses are unavoidable. If an excess of selenium is used, pink glasses are obtained that used to be important for artistic purposes.

The addition of cadmium sulfoselenide to glass gives intense colors such as those required for signal technology (e.g., traffic lights). The

colors vary from yellow to red, depending on the CdSe content and melting conditions. Because of the volatility of selenium compounds, reproducible color control is difficult.

Pigments (→ Pigments Inorganic, Chap. 3.2.). Selenium is used as a pigment in the form of cadmium sulfoselenide. Replacement of part of the sulfur in cadmium sulfide by selenium changes the yellow color to an intense red. The pigment has good brightness and high stability. It is an important colorant for plastics, because the addition of up to 1.5 % cadmium sulfoselenide does not significantly affect their physical properties; it is also stable at the temperatures used for injection molding and extrusion. However, the importance of these pigments has declined considerably because of the toxicity of cadmium compounds. In some areas, the use of cadmium sulfoselenide is prohibited.

Metallurgy. The addition of selenium to steel improves its machinability, resulting in higher cutting speeds, lower energy consumption, and a longer lifetime for the machine tool. Although this is often achieved by adding sulfur, selenium is always used where good hot and cold formability, corrosion resistance, and surface finish are also required. For stainless steel, the addition rate is ca. 0.1 – 0.3 % Se. The machinability of copper can also be improved by addition of selenium, but tellurium is used more often. Addition of up to 0.1 % selenium to magnetic silicon steels improves their magnetic properties for use in transformer cores. Selenium is also used in lead accumulators to improve the casting and mechanical properties of lead – antimony alloys with low antimony content.

Ferroselenium, copper selenide, and nickel selenide are used in metallurgy.

Agriculture. Although the toxicity of soil with high selenium content has long been known, only much later was the need for selenium as an essential trace element in low concentrations discovered. A number of diseases formerly thought to be due to vitamin E deficiency are in fact the result of a deficiency of selenium. For example, the addition of 0.1 – 0.3 ppm selenium to the feed of chickens and pigs considerably increases their growth rate and prevents certain diseases, although the mechanism of this is not fully understood. Selenium may act as an antioxidant or free-radical trap.

The high rate of heart disease in Finland is thought to be due to a selenium deficiency, the soil being low in selenium, and the law now requires that 6 – 16 g/t selenium be added to fertilizers used there.

Selenium is added to fertilizers or animal feed in the form of sodium selenite or sodium selenate, which are absorbed more readily by plants.

Other Uses. Selenium and selenium compounds (e.g., Selenac, dialkylselenium carbamates) are added with sulfur in rubber manufacture. This improves the thermal stability of the product and controls the vulcanization rate.

Selenium compounds are used to a small extent as additives to oxidation catalysts for hydrocarbons. Selenium dioxide is also used as a selective oxidizing agent in organic chemistry.

Selenium acts as an absorbent for mercury, forming stable mercury selenide, in gas purification [27].

Addition of up to 5 % selenium has been proposed in the preparation of dental amalgams [28].

7. Quality Specifications and Analysis

Standard-grade selenium containing 99.5 % Se is adequate for chemical and metallurgical use, although many producers supply a 99.9 % Se material. A special pigment grade containing 99.8 % Se is also marketed. The standard grades are supplied as powders of various bulk densities, depending on precipitation conditions. The standard grade is used mainly as starting material for the production of high-purity selenium for photocopiers and electronic applications, which require a product containing > 99.999 % Se. Here, the heavy-metal content must also be as low as possible, and the oxygen content should be much less than 5 ppm. Electronic-grade selenium is supplied in the form of granules, which can be produced by pouring molten selenium into deionized water. In addition to chemical analysis, the quality assessment of high-purity selenium includes mea-

surement of electrical and especially the photoelectrical properties [29]. The crystallization temperature, determined by thermal analysis, can give a useful indication of the impurities in selenium (Fig. 2), although interpretation of the results is not always unambiguous.

The methods of analysis for selenium depend on the matrix material. Direct spectroscopic determination in raw materials and intermediate products is usually impossible due to lack of standards. Hence, selenium-containing materials are first treated with nitric or sulfuric acid, for example, to dissolve the selenium as selenous acid. Most methods of determination involve reduction of selenous acid with various reducing agents, usually in solution in strong hydrochloric acid. Selenium can be determined gravimetrically after reduction with iron(II), for example, if the hydrochloric acid concentration is such that precipitation is complete and no loss of $SeCl_4$ vapor occurs [30]. The precipitated selenium is weighed, or redissolved and determined by atomic absorption spectroscopy, inductively coupled plasma, or direct coupled plasma spectroscopy [31]. In one of the oldest methods still in use, selenous acid is titrated with thiosulfate according to the equation:

$$Na_2SeO_3 + 4\,Na_2S_2O_3 + 6\,HCl \longrightarrow Na_2SeS_4O_6 + Na_2S_4O_6 + 6\,NaCl + 3\,H_2O$$

Sodium monoselenopentathionate is formed, and the excess of thiosulfate is back-titrated iodometrically [32].

8. Selenium Compounds

Selenium forms a large number of chemical compounds, some of which are of major industrial importance.

Selenium Dioxide, Selenous Acid, Selenites. Volatile selenium dioxide (sublimes at 315 °C) is formed by the combustion of selenium-containing materials. Selenium dioxide [*7446-08-4*] dissolves readily in water (800 g/L at 85 °C) to form selenous acid [*7783-07-5*]. Unlike sulfur dioxide, selenium dioxide and selenous acid are easily reduced to selenium by reducing agents such as sulfur dioxide. Even traces of organic material reduce part of the selenium dioxide to selenium, resulting in a slightly reddish color of the SeO_2. The sensitivity to reduction is increased by the influence of light. Selenium dioxide is used to oxidize alkyl groups to carbonyl groups in organic chemistry, as a lubricant additive, and as an additive in the electrolysis of manganese. Selenous acid is more stable than sulfurous acid and can be isolated in the pure state in the form of colorless prisms. Selenous acid decomposes above 70 °C, forming selenium dioxide and water. Sodium selenite [*10102-18-8*], zinc selenite [*13597-46-1*], and barium selenite [*13718-59-7*] are important additives in glass manufacture. These salts are prepared by the reaction of selenous acid with the corresponding hydroxides or oxides, followed by crystallization.

Selenium Trioxide, Selenic Acid, Selenates. Selenous acid is oxidized to selenic acid [*7783-08-6*] by strong oxidizing agents such as chlorine, chloric acid, ozone, or anodic oxidation. Selenic acid is a hygroscopic solid that melts at 59.9 °C. It is a much stronger oxidizing agent than sulfuric acid; for example, a mixture of concentrated selenic acid with concentrated hydrochloric acid evolves chlorine. Selenic acid can be dehydrated with phosphorus pentoxide or by applying vacuum (200 Pa) at 160 °C to give the strongly oxidizing selenium trioxide [*13768-86-0*] (*mp* 118 °C). Above 185 °C, selenium trioxide decomposes into selenium dioxide and oxygen. Selenates are formed by the reaction of selenic acid with metal oxides or hydroxides, and resemble the isomorphous sulfates in both structure and solubility. Sodium selenate [*13410-01-0*] has become an important fertilizer additive.

Hydrogen Selenide, Selenides. Hydrogen selenide [*7783-07-5*] can be obtained either directly from the elements at ca. 400 °C or by decomposition of the selenides of iron, magnesium, or aluminum with hydrochloric acid. It is a colorless gas (*bp* −41.3 °C) smelling like rotten radishes, is even more toxic than hydrogen sulfide, and has a very irritating effect on the mucous membranes, causing bronchial and nasal irritation. Hydrogen selenide is less stable than hydrogen sulfide and can be oxidized to selenium by air, especially in the presence of light. Heavy-metal selenides such as copper selenide

form the basis of selenium extraction from ores. Cadmium selenide [*1306-24-7*], produced from cadmium and selenium, is used in the pigment industry together with cadmium sulfide.

High-purity zinc selenide [*1315-09-9*] is an important infrared optical material. Single crystals can be produced by reacting zinc vapor with hydrogen selenide (chemical vapor deposition, CVD). Copper indium selenide could be the basis for solar cells of the future; light efficiencies of 14 % at an energy flux density of $> 100\,W/m^2$ can be achieved. However, the manufacturing process (CVD) is expensive [23, 33].

Selenium disulfide [*7488-56-4*] is formed by reaction of hydrogen sulfide with selenous acid or by direct combination of the elements. The red powder (*mp* ca. 100 °C) is used in concentrations of < 1 % in shampoos and hair preparations for the treatment of dandruff.

Selenium Halides. The action of halogens or halides on elemental selenium yields various selenium halides, depending on the temperature and stoichiometric ratio. Selenium monochloride [*14457-70-6*], Se_2Cl_2 (ϱ 2.774 g/cm^3), and selenium monobromide, Se_2Br_2 (ϱ 3.604 g/cm^3), are intensely colored, heavy liquids. $SeCl_4$ [*10026-03-6*] and $SeBr_4$ [*7789-65-3*] are crystalline substances that readily form complexes with alkali-metal halides. Selenium exhibits the oxidation state +VI only in SeF_6 [*7783-79-1*], the corresponding chloride and bromide being unstable. Of the oxyhalides, seleninyl chloride [*7791-23-3*], $SeOCl_2$, is liquid at room temperature and is remarkable for its extreme reactivity, combining with almost all elements.

Organic Selenium Compounds. Like sulfur, selenium forms a large number of organic compounds and can be a component of aliphatic, aromatic, and heterocyclic compounds. From the simple selenols (RSeH), which correspond to the alcohols, to the amino acids, enzymes, and proteins, a large number of selenium-containing organic compounds are known, several of which are of biological importance. The starting compounds for the introduction of selenium into organic compounds are often dialkyl selenides (R_2Se) or dialkyl diselenides (R_2Se_2), which are formed from the corresponding alkyl halide and sodium selenide:

$$2\,RBr + Na_2Se \longrightarrow R_2Se + 2\,NaBr$$
$$2\,RBr + Na_2Se_2 \longrightarrow R_2Se_2 + 2\,NaBr$$

9. Economic Aspects

The total consumption of selenium in 1989–1991 was ca. 2100–2300 t/a (Table 1) [22, 34]. Average consumption in previous years was ca. 1700 t/a, although the published figures are unreliable due to the lack of information from Eastern European countries. Of the total, about one-third is produced as high-purity selenium for electronic applications. Since selenium is a byproduct of copper production, its price is subject to very wide variations due to over- or underproduction from time to time. The price of selenium has decreased considerably (see Table 1). However, most dealing takes place not on the open market, but directly between the producer and consumer, so the true prices differ from the published prices. The price for standard-grade selenium in 1990 was ca. \$ 10/kg, and for high-purity selenium ca. \$ 30–50/kg [22]. Manufacturers of elemental selenium in the Western world include the large copper producers Noranda Mines (Canada); Norddeutsche Affinerie AG (Germany), with its subsidiary Retorte producing selenium compounds and high-purity selenium; Metallurgie Hoboken-Overpelt (Belgium); Mitsubishi Metals, Nippon Mining, Sumitomo (Japan); Outokumpu (Finland); ASARCO, Kennecott, and Phelps Dodge (United States) [35]. Selenium compounds are also produced by Degussa (Germany).

Although the consumption of selenium compounds in the glass industry and as a fertilizer additive is increasing, the use of cadmium selenide in pigments is decreasing, and selenium is being replaced by organic photoconductors in some types of xerography. Therefore the total consumption of selenium is not expected to increase in the near future. However, the supply of selenium could decrease in the future if copper is produced partly by hydrometallurgical processes, which do not yield a selenium byproduct.

10. Biological Activity and Toxicology

Although selenium is an important trace element in low concentrations, it is toxic at higher concentrations. It is an essential trace element in the selenoenzyme glutathione peroxidase. This enzyme, together with vitamin E, is important for the protection of cells from oxidative attack. The activity of glutathione peroxidase in red blood corpuscles correlates well with the selenium concentration up to 100 µg/L [37, 38]. Low selenium levels in the blood cause heart disease. For instance, in China, Keshan disease, a cardiomyopathy, caused the deaths of a large number of people, especially children, until the daily consumption of selenium was found to be very low. The transition from essential trace quantities to toxic quantities of selenium in terms of intake in food is summarized below [38]:

Low-selenium area with Keshan disease	11 µg/d
Selenium adequate area	116 µg/d
National Academy of Sciences, Food and Nutrition Board "safe and adequate" range	50 – 200 µg/d
Lowest observed effect level (LOEL)	3200 µg/d
High-selenium area with chronic selenosis	4990 µg/d

The concentration of selenium in the blood should be 60 – 100 µg/L. Although small amounts of selenium may reduce the risk of cancer, as indicated by some investigative studies, this has not been proved conclusively.

A chronic high selenium intake of > 5 mg/d gives rise to nonspecific symptoms such as hair loss, changes to the fingernails, diarrhea, effects on the central nervous system, and nonspecific changes to the liver. Also, a loss of appetite and a tendency to walk in a circle can occur. High concentrations of selenium in the workplace can cause headaches and "selenium catarrh." Also, the breath can have a garliclike smell due to the formation of methyl selenide, although this effect is much less pronounced than with tellurium.

A few selenium compounds exhibit acute toxicity. Irritation of the mucous membranes of the digestive system, liver damage, and toxic edema of the lungs have been observed. The most toxic compound is hydrogen selenide, for which the MAK is 0.05 ppm, the MAK value for other selenium compounds being 0.1 ppm. In the United States, the TLV is 0.2 mg/m^3. In a study carried out in Canada on people working in selenium production, if the TLV was exceeded slightly (up to 0.8 mg/m^3) for limited periods, no symptoms resulted [39]. In Germany, the limit in drinking water is 0.008 mg/L [40], and in the United States, the EPA recommends a maximum contamination level (MCL) of 0.01 mg/L.

Table 1. Estimated production (t), consumption (t), and price ($/kg) of selenium [22, 35]

	1989	1990	1991	1995*

1. Definition of Semiconductors

Semiconductors are crystalline materials whose electric resistivity is between that of insulators and conductors (i.e., in the approximate range 10^9 to $10^{-3}\,\Omega\cdot\mathrm{cm}$). In general, insulators include glass, rubber, plastics, etc., and conductors are metals.

Besides electric resistivity, semiconductors have three major characteristics:

1) The resistivity decreases with increasing temperature, which is substantially different from metals.
2) Not only is the current – voltage relation inconsistent with Ohm's law, but the curve is also nonsymmetrical with respect to the origin. This results in the rectifying action of semiconductors.
3) The conductivity of a semiconductor is extremely sensitive to impurities even at the part-per-million (ppm) level or lower. This specific feature is the most important factor for the commercial use of semiconductors in the electronics industry.

2. History

In the mid-1800s, M. Faraday, F. Braun, and others discovered crystals that have the specific features mentioned in Chapter 1. The rectifying action of selenium was discovered in 1876 by Adams. Although classical physics could not interpret semiconductor phenomena theoretically, the commercial application of selenium and copper(I) oxide in rectifiers and crystal detectors began in Europe in the 1920s without knowledge of the theory. The crystal detector played a very important role in the 1930s, because its rectifying action helped to amplify the weak current of radio broadcasting.

The development of quantum mechanical theory in the 1920s helped to interpret the behavior of semiconductors. In 1931, A. H. Wilson applied quantum theory to semiconductors and established a basic theoretical model (Wilson model). This theory was developed further by A. Schottky and others.

However, the theory was not confirmed experimentally at this time because purification technologies for the experimental materials required were inadequate and the materials did not exhibit their inherent properties. During World War II, the development of radar became an urgent problem, and countries such as the United States, United Kingdom, Germany, and Japan attempted to develop low-noise crystal detectors, for which ultrahigh-purity materials were essential. They selected silicon and germanium, and succeeded in obtaining very pure germanium crystals before the end of the war. This was followed by the discovery of the transistor effect by J. Bardeen and W. H. Brattain in 1948 and the principle of the $p-n$ junction by W. Shockley in 1949 at Bell Laboratories in the United States. Due to its higher melting point and chemical reactivity, silicon is more difficult to process than germanium, and development was therefore delayed. However, with the progress of metal oxide technology for making the insulating layer, silicon became the main semiconductor material. Since the 1950s, silicon semiconductor devices such as diodes, transistors, and integrated circuits (ICs) have been developed, and the density of integration has increased astronomically. The group III – V compounds developed by H. Welker in 1952 have become commercially established primarily in optoelectronics (→ Electroluminescent Materials and Devices).

3. Theory

3.1. Structure of Semiconductor Crystals

A typical semiconductor material is silicon. Silicon is an element of group IV of the periodic table, and in the crystal the four electrons in the outermost orbital of an atom form covalent bonds with adjacent atoms, resulting in a stable crystal. The silicon crystal consists of a diamond-type lattice in which four adjacent atoms form the cubic-system tetrahedron shown in Figure 1. Perfect silicon crystal is an insulator because no free mobile electrons exist. Conductivity is imparted to the silicon crystal by crystal defects, residual impurities, or free electrons generated by doping with impurities. However, the conductivity is much lower than that of metals.

Figure 1. Tetrahedral structure of diamond

Metal atoms have free mobile electrons within the crystal. Because a metal crystal tends to form a close-packed structure, electrons of the outermost orbital of each atom are isolated and are present as free electrons, which are responsible for conductivity. Consequently, a metal atom does not have specific electrons, and the atom exists as the cation.

3.2. Conduction Mechanism of Semiconductor Materials

3.2.1. Band Model

The conduction mechanism of semiconductor materials can be interpreted by band model theory, which is a statistical – mechanical extension of the atomic model proposed by Bohr in 1913. Bohr proposed that electrons surrounding an atomic nucleus can exist only in specific orbitals. When this theory is extended to a crystal – a congregation of atoms – the specific orbitals in which electrons exist can be considered as a band that has a certain width.

When silicon atoms are arranged in an ordered crystal, the band in which electrons exist is called the valence band (see Fig. 2). The arrangement depends on the crystal and the lattice constant, which is related to the energy level of the valence band. If energy such as heat or light, which is higher than the covalent bond energy of the crystal, is supplied, the valence electrons are activated and jump to a higher band. This higher band level, in which the electrons are freely mobile and can participate in the conduction of electricity, is known as the conduction band. The zone between the two bands, in which electron occupancy is forbidden by virtue of quantum theory, is called the forbidden band or band gap. The width of the band gap corresponds to the energy required to break a covalent bond and depends on the atoms and their arrangement. The band gaps of insulators are much wider than those of semiconductors, whereas metals can be defined as materials whose band gap is zero.

When an valence electron jumps to a higher level, a hole is formed in the valence band. This hole is freely mobile within the valence band, behaving as a positively charged particle and participating in the electrical conductivity of a semiconductor together with the free electron in the conduction band.

Based on the above theory, the conductivity of semiconductors can be described by

$$a = nq\mu_{\mathrm{e}} + pq\mu_{\mathrm{p}} \tag{1}$$

where

a = conductivity
n = concentration of electrons
p = concentration of positive holes

Figure 2. Band model

q = charge of an electron
μ = mobility of an electron (μ_e) or positive hole (μ_p) in a unit electric field

At thermal equilibrium, $n = p$.

The mobility depends on the bonding state of the crystal lattice and the material itself, and is less at higher temperature because the electrons tend to collide with atoms due to the increased atomic vibration resulting from the higher thermal energy of the crystal. In general, a positive hole is less mobile than an electron.

On the other hand, n and p increase exponentially with increasing temperature in accordance with the law of mass action.

$$np \sim e^{-E/kT} \tag{2}$$

where E is the band gap energy, k the Boltzmann constant, and T the absolute temperature.

Because the increase of n and p with temperature is much larger than the decrease in μ, the conductivity of semiconductors increases with increasing temperature. In the case of metals, since the electrons in the outermost orbitals always act as free electrons, n is independent of temperature and μ decreases with temperature. Hence the conductivity of metals decreases with increasing temperature.

Mobility is also affected by impurities in the crystal. Positively charged impurities attract and deflect electrons, and thus decrease the mobility. Therefore, historically, the measured value of mobility of various semiconductors increased from year to year until the late 1950s because of the improvement in crystal quality. Even now, the crystals of compound semiconductors still have fairly high contents of crystal defects and impurities. Therfore, the measured mobility is not necessarily the inherent mobility of each material.

3.2.2. Doping

As discussed above, the electric conductivity of semiconductors is the result of electrons jumping up to the conduction band and the vacant positive holes that remain in the valence band. In contrast to the vacuum tube, which utilizes thermal excitation, impurity implantation is used to generate free electrons and positive holes in semiconductors, and this process is known as doping.

If a group V element such as arsenic, phosphorus, or antimony is implanted in silicon (group IV) crystal, four out of five electrons in the outermost orbital of a group V element remain in the valence band by bonding to adjacent silicon atoms, but the remaining electron is freely mobile in the crystal and jumps up to the conduction band on thermal excitation. A semiconductor that contains many negatively charged electrons is known as an n-type semiconductor.

On the other hand, when a group III element such as boron, aluminum, or gallium is implanted in silicon, a positive hole is formed because a group III element has only three electrons in the outermost orbital. A semiconductor of this type is called a p-type semiconductor. Because of this mechanism, a group V dopant

Figure 3. Donor and acceptor

is called a donor (of electrons) and a group III dopant is known as an acceptor (Fig. 3).

Impurities and defects in a crystal generate free electrons and positive holes. Therefore, to achieve very fine control, a defect-free single crystal of extremely high purity must be made, and the dopant implanted quantitatively.

3.2.3. The *p – n* Junction

The $p-n$ junction is the basic structure of semiconductor devices. As shown in Figure 4, the $p-n$ junction is an interface of a p-type and an n-type semiconductor crystal. Each domain contains many free electrons or positive holes. If the $p-n$ junction is forward biased, positive holes move to the n-domain and electrons to the p-domain, where they remain as minority carriers and contribute to conduction until they recombine with majority carriers and reach thermal equilibrium.

The concentration of minority carriers entering the other side, Δp and Δn, depends on the voltage as follows:

$$\Delta p, \Delta n \sim \mathrm{e}^{aV/kT} \tag{3}$$

a = conductivity
V = voltage
k = Boltzmann constant
T = absolute temperature

Therefore, Δp and Δn increase exponentially with voltage.

If the $p-n$ junction is reverse biased, positive holes move to the cathode and electrons to the anode, and a so-called depletion layer is formed in the vicinity of the junction. Therefore, very few minority carriers cross the junction, and the backward electric current is negligible compared to the forward current. Because of this feature, the $p-n$ junction exhibits a strong rectifying characteristic, as shown in Figure 5. When the reverse voltage reaches a very high level (e.g., several tens of volts), a high current is generated by the electron avalanche phenomenon.

3.3. Lifetime and Recombination of Charged Particles

Implanted minority carriers recombine with existing majority carriers and restore the original thermal equilibrium condition. This interval is called the lifetime of the charged particles (numerically, the lifetime is defined as the time constant of the exponential damping curve). The lifetime depends on the type of crystal and is generally $10^{-6}-10^{-3}$ s. However, recombination does not occur only between electrons and positive holes; various defects and impurities in the crystal often act as recombination centers. They decrease the apparent lifetime of a crystal. Therefore, as in the case of mobility and doping, the production of high-purity, defect-free single crystals is the basic requirement of the semiconductor industry.

3.4. Effect of Various Factors on Semiconductors

3.4.1. Effect of Radiation

If a semiconductor is irradiated by light whose photoquantum energy is higher than the band

Figure 4. $p-n$ Junction

Figure 5. Rectifying action of a $p-n$ junction

gap energy of the semiconductor, an electron – positive hole pair is formed by excitation and the conductivity increases (photoconductivity). If the pair is formed near a $p-n$ junction, photoelectromotive force is generated. This is the principle of the photocell. Ionizing radiation (X-ray, β, or γ) also releases electrons in a crystal and forms electron – positive hole pairs. If a semiconductor is irradiated by higher-energy particles such as protons, α-particles, or neutrons, crystal defects are formed and performance deteriorates. Group III – V materials such as GaAs have better radiation hardness than silicon, which is an advantage in their use as solar cells for satellites that are affected by cosmic rays.

3.4.2. Behavior in a Magnetic Field

If a semiconductor crystal is placed in an electric field and a magnetic field is applied perpendicular to the direction of the electric current, an electric field is generated in a direction perpendicular to both the electric current and the magnetic field. This is called the Hall effect. The Hall voltage depends on the concentration of charged particles and the electron mobility. Therefore, the concentration of charged particles and the type of conduction (n- or p-type) can be determined by measuring the Hall voltage. A device utilizing the Hall effect is used for magnetically operated switches in rotary machines and made mainly from GaAs or InSb.

3.4.3. Behavior under High Electric Field

Under high electric fields, semiconductor materials often exhibit anomalous behavior. This includes the tunnel effect, Zener breakdown, and the Gunn effect. When the dopant concentrations in the n- and p-domain of a $p-n$ junction are both very high (e.g., $>10^{18}$ cm^{-3}, p^+-n^+ junction), the depletion layer formed by the very low reverse bias becomes extremely narrow and a high voltage arises due to the generation of negative resistance. Under these conditions, electrons in the p-domain can pass through the depletion layer to the n-domain as a wave and move as particles in the n-domain. This phenomenon – rapid conversion of particle to wave and then wave to particle – is called the tunnel effect, and the resulting abrupt increase of current is known as Zener breakdown. The tunnel diode is used for high-speed switching, and the Zener diode is used for voltage control.

Semiconductors whose band structure is of the direct-transition type (→ Electroluminescent Materials and Devices, Chap. 2.), such as GaAs and InAs, tend to generate high-resistance layers when the electric field increases; electrons then move from one conduction band to the other because the mobility of electrons differs greatly between the two conduction bands. For this reason,an oscillation phenomenon called the Gunn effect is observed in the microwave region, and is used for amplification and oscillation of microwaves and for shaping of pulse waves.

3.4.4. Semiconductor – Metal Contacts

Semiconductor – metal contacts are a basic structure of semiconductor devices, and the properties of the contact play an important role. Among the many historical hypotheses regarding the contact, the Schottky barrier model explains its properties fairly reasonably. As shown in Figure 6, SCHOTTKY proposed that an electrical dual layer is formed at the contact, with negative charges distributed on the surface of the semiconductor and positive charges distributed within the semiconductor. Since a metal possesses many free electrons, the electric potential inside the metal is uniform and, therefore, an ordered arrangement of charges cannot be maintained. When electrons pass the dual layer, they must overcome the barrier at the contact, and the height of this barrier was regarded as the difference in work function generated by the contact:

$$\begin{aligned}&\text{Height of Schottky barrier}\\&= \text{Work function of semiconductor}\\&\quad - \text{Work function of metal}\end{aligned}$$

However, when the electrical properties of various metal – semiconductor contacts were measured, these properties were found not to depend on the metal but to be strongly affected by the treatment of the semiconductor surface.

To solve this problem, J. BARDEEN proposed, as shown in Figure 7, that at the surface of a semiconductor an inherent quantum mechanical layer exists that traps electrons. Consequently, positive charges remain inside the semiconductor as an electrical dual layer. This hypothesis was experimentally verified by BRATTAIN and led to the invention of the point-contact transistor.

Figure 6. Schematic diagram of the electric dual layer of a metal – semiconductor contact

Figure 7. Surface states of a semiconductor (Bardeen's theory)

The behavior of a semiconductor surface is very complicated. For making devices, only the thin surface layer of a wafer is actually used. Therefore, polishing and treatment of the wafer surface are very important.

Although the Schottky barrier theory was disproved, diodes with metal – semiconductor contact structure are called Schottky barrier diodes and are important high-speed devices for use in the microwave and ultrahigh-frequency range.

4. Materials, Properties, and Manufacture

4.1. Outline

4.1.1. Requirements for Commercial Use

The following conditions are important for the commercial use of semiconductor materials as electronic devices:

1) The $p-n$ junctions can be made practically
2) Semiconductor properties should be retained up to at least 150 °C
3) The mobility of electrons and positive holes must be high
4) The diffusion length of the carrier must be high ($\geqq$ 0.1 mm)

Silicon is used overwhelmingly for most of the high-volume devices (→ Silicon), followed by group III – V compounds (GaAs, GaP, etc.), which are used mainly for optoelectronic devices such as light-emitting diodes (LEDs), laser diodes (LDs), and some special microelectronic devices. Germanium used to be a very important material and was the first to be used commercially. However, it was replaced by silicon, which offers much better performance and lower cost; germanium is now used only for limited purposes. Other materials such as group VI amorphous metals, multicomponent chalcogenides, and oxides have specific uses.

Academic attention has been paid to organic semiconductor materials because of their unique properties; tetracyanoquinodimethane (TCNQ) has been used commercially for organic condensers.

Important properties of major semiconductor materials are listed in Table 1.

4.1.2. Properties and Uses

4.1.2.1. Group IV Elements

4.1.2.1.1. Germanium

Germanium was used for crystal detectors before World War II, and in 1948 the first transistor was made from germanium by J. Bardeen, W. H. Brattain, and W. Shockley. Therefore, germanium was a key material for diodes and transistors. Nowadays, small amounts are used for specific diodes.

The band gap of germanium is 0.66 eV, which is lower than that of silicon (1.08 eV) or GaAs (1.4 eV). This means that the upper temperature limit to which germanium retains its semiconductor characteristics is ca. 100 °C, compared to 200 °C for silicon. Since the reverse breakdown voltage of the germanium $p-n$ junction is also lower than that of silicon, it cannot compete with the latter in high-voltage power uses.

However, a low energy gap results in a low starting voltage in the forward voltage – current property, which is advantageous for small signal diodes. The electron and positive hole mobility of germanium is three and four times higher than that of silicon and GaAs, respectively. This gives better performance in high-frequency devices. However, because it is compensated for by improvement of the device structure, germanium has been replaced by silicon even in this market.

The transparency of germanium to light extends up to a wavelength of 1.8 μm, compared with 1.1 μm for silicon. Therefore, germanium avalanche photodiodes are used as detectors in optical fiber communication. However, with the development of quartz optical fiber and InGaAs avalanche photodiodes, germanium is gradually being replaced by these products.

Germanium polycrystal is made by reduction of high-purity GeO_2, obtained from zinc smelting sludge, and purification by natural solidification and zone melting. For production of a single crystal, a horizontal zone leveling process is normally used. If especially high purity is required (e.g., for use in avalanche photodiodes and γ-ray detectors), the Czochralski pulling process is employed as in the case of silicon (→ Silicon).

Table 1. Physical properties of semiconductor materials

Material	Lattice constant, nm	Crystal∗ structure	*mp*, °C	Band gap energy, eV	Type of transition ∗∗	Mobility, $cm^2 V^{-1} s^{-1}$	
						Electron	Positive hole
Diamond		D		5.5		2000	2100
Si	0.5431	D	1420	1.11	I	1500	450
Ge	0.5646	D	936	0.66	I	3900	1600
GaAs	0.5654	Z	1238	1.43	D	8800	400
AlAs	0.5662	Z	≥ 1700	2.16	I	1000	≤ 100
GaP	0.5451	Z	1465	2.26	I	300	
InP	0.5869	Z	1062	1.35	D	4600	150
ZnS	$a = 0.381$, $c = 1.244$	W	1830	3.66	D	160	10
ZnSe	0.5668	Z	1520	2.67	D	600	40
CdTe	0.6481	Z	1090	1.50	D	1050	80
SiC	$a = 0.309$, $c = 1.512$	W	2800	2.996	I	400	50

∗ D = diamond structure; Z = sphalerite structure; W = wurtzite structure.
∗∗ D = direct transition; I = indirect transition.

4.1.2.1.2. Diamond

Diamond has a very high band gap energy (5.5 eV), and the mobility of both electrons and positive holes is also high compared to other semiconductor materials (see Table 1). In addition, since its other properties such as low dielectric constant and high thermal conductivity are advantageous for use in high-speed devices, the use of diamond in heat-resistant devices, short-wavelength LEDs, and high heat-generating power devices is desirable. However, the formation of a conductive $p-n$ junction and the formation of a single-crystal layer, especially on a silicon substrate, have not been achieved. The application of buckminsterfullerene as a semiconductor is being studied, but is still in the exploratory stage.

4.1.2.2. Others

4.1.2.2.1. Group VI Elements

Crystalline and amorphous selenium and tellurium are members of group VI. Their crystal structures belong to the trigonal system. Single crystals of selenium in the form of needles are normally made by sublimation as needle crystals, and tellurium single crystals are made by the Bridgman process or the rotational pulling process. Both selenium and tellurium are electrically *p*-type, and bismuth and antimony are used as dopants. A selenium layer made by vacuum deposition is used for making rectifiers (→ Selenium and Selenium Compounds), in which a heterojunction between an *n*-type CdSe and a *p*-type selenium layer is utilized as the rectification junction. Amorphous semiconductor selenium is made either by high-speed quenching of the melt or by vacuum deposition. Amorphous selenium has lower optical absorption and reflectivity, and is photoconductive. High-purity amorphous selenium made by vacuum deposition is used for xerography.

4.1.2.2.2. Multicomponent Chalcogenides

The main components of chalcogenides are group IV chalcogen atoms; examples include Ge – As – Te and Se – Ge. Thin layers are made by vacuum deposition or sputtering. Applications of these materials are:

1) Switches and memories utilizing a large change of electrical resistance on phase transition
2) Optical memories utilizing changes in reflection factor, transmittance, and refractive index or photodoping
3) Resist materials utilizing a combination of photodoping and photodarkening

4.1.2.2.3. Oxide Semiconductors

In general, oxide compounds exhibit semiconductor characteristics if their composition is made nonstoichiometric by reduction or oxidation. Examples of the former are ZnO, TiO_2,

CdS, and SnO_2 (*n*-type) and, of the latter, NiO, FeO, and Cr_2O_3 (*p*-type). Applications of oxide semiconductors are gas sensors (SnO_2), ballistors (ZnO), and ceramic condensers ($BaTiO_3$).

4.1.2.2.4. Organic Semiconductors

An organic semiconductor is an organic or high molar mass compound that exhibits conductivity and other semiconductor characteristics. The π-electrons or unpaired electrons contribute to conductivity. Polycyclic aromatic compounds, such as anthracene, and compounds containing conjugated double bonds, such as phthalocyanine and polyacetylene, are π-electron carrier types, whereas charge-transfer complexes and organic compounds that contain free radicals are unpaired-electron carrier types. Examples of charge-transfer complexes are complexes of perylene with iodine or sodium. In 1962, tetracyanoquinodimethane (TCNQ) was announced as a strong acceptor whose conductivity is competitive with inorganic materials (several kS/cm) [7]. TCNQ has good high-frequency performance and is used commercially as a raw material in condensers for notebook or laptop personal computers and handheld video cameras in Japan. The chemical structures of perylene and TCNQ are shown in Figure 8.

Figure 8. A) Tetracyanoquinodimethane (TCNQ); B) Perylene

Organic semiconductors are now being evaluated for use as photoconductive and photochromic materials, high-energy converters, heat – electricity converters, and in piezoelectricity. Because they exhibit different functions when minor changes are made in their chemical structure, various possible commercial application exist. However, their electron mobility is much lower than that of inorganic semiconductors, and most of them are not used commercially.

4.2. Compound Semiconductors

4.2.1. Properties

Compound semiconductors are intermetallic compounds between groups III and V, II and VI, or IV and IV elements. Examples are GaAs, GaP, InP, InSb, AlGaAs (III – V); ZnS, ZnSe, CdS, CdTe (II – VI); and SiC (IV – IV). Among these, GaAs, GaP, and InP have been developed because of the expanding market for opto- and microelectronic devices such as light-emitting diodes, laser diodes, and field-effect transistors (FETs). With the progress of epitaxial growth processes and device processing technology, mixed crystals such as AlGaAs and InGaAsP have been developed as specialty products.

Specific features of compound semiconductors are as follows:

1) The charge carrier mobility of group III – V compounds is generally several times higher than that of silicon. Hence, GaAs is being developed for devices with high speed, high frequency, low noise, and low electricity consumption.
2) The energy band structure of GaAs, InP (III – V), CdTe, ZnSe (II – VI), etc., is of the direct-transition type; therefore, their efficiency of light emission is higher than that of silicon or germanium, whose energy band structure is of the indirect-transition type. Thus, these compound semiconductors are used widely as optoelectronic devices for information processing and optical communication. GaP became a key material for visible LED with the development of nitrogen-doping technology [8].
3) The emission of electrons by GaAs when exposed to electromagnetic radiation (photoelectric effect) is utilized in photodiodes and solar cells.

4) The broad band gap width of GaAs helps to improve high-temperature performance and radiation hardness against cosmic rays.
5) By preparing mixed crystals such as AlGaAs and InGaAsP, the band gap width and lattice constant can be changed over a fairly broad range. Various mixed crystals are used as raw materials for high-performance devices with specific properties.
6) SiC (IV – IV) is used commercially as the raw material for blue LEDs (→Electroluminescent Materials and Devices, Chap. 4.2.).

4.2.2. Single Crystals

The single crystals of compound semiconductors are generally manufactured by either the boat-grown or the liquid-encapsulated Czochralski method. Here, the manufacturing methods of GaAs are described as representative of group III – V semiconductors.

4.2.2.1. Boat-Grown (BG) Method

There are two boat-grown (BG) methods: the gradient freeze (GF) and the horizontal Bridgman (HB), shown in Figures 9 and 10. Both methods use a quartz boat in which either gallium and arsenic or GaAs polycrystals are charged. Molten GaAs is cooled gradually from one end, and a single crystal grows from the seed crystal. In the GF process, the temperature of the entire system is lowered slowly while the temperature gradient is kept constant. In the HB process the boat moves through an electric furnace in which the temperatures T_1, T_2, and T_3 are kept constant.

Generally, the HB process uses GaAs polycrystal, which is made separately, whereas in the GF process, polycrystalline GaAs is synthesized by subliming arsenic on to gallium in the quartz boat. The growth direction of a single crystal is normally (111), but (511) is also used in some cases.

The vertical Bridgman (VB) method (Fig. 11) is used for the manufacture of GaAs and CdTe single crystals. In the process, a temperature gradient is formed in the vertical-type furnace, and the ampule containing polycrystal moves vertically to grow the single crystal. Neither the HB nor the BG process can make round wafers. However, the VB process can be used to make round wafers by means of a cylindrical ampule because the growth direction is (100). Although VB is still in the developmental stage, it is important as a method of making integrated circuit (IC) grade, large, round, low-defect wafers.

Figure 9. Gradient freeze method

Figure 10. Horizontal Bridgman method

High purity and low defect concentration are two main technological targets of single-crystal manufacture. Silicon contamination is a problem in the BG method, because a quartz boat is generally used. Using 6 N or 7 N gallium and arsenic results in GaAs containing $(5-10)\times10^{16}$ cm^{-3} silicon. For use in optoelectronic devices, where Si-doped *n*-type or Zn-doped *p*-type GaAs is used, silicon contamination can be compensated by adjusting the amount of dopant. However, for use in microelectronic devices such as FETs and ICs, silicon must be compensated by chromium, which forms a deep acceptor level.

To make low-defect crystals, a mild temperature gradient, lower growth temperature, and precise stoichiometry control must be consid-

ered. Of the BG methods, GF is superior to HB as far as defect content is concerned. The typical etch pit density (EPD) of BG wafers is 3000 – 5000 (Si doped and Zn doped) or 5000 – 6000 (Cr doped), and they are generally accepted on the market. Ingots made by the BG method are generally 300 – 500 mm long, and the wafer diameter is 2 – 3 inches.

Figure 11. Vertical Bridgman method
PBN = pyrolytic boron nitride

4.2.2.2. Liquid-Encapsulated Czochralski (LEC) Method

In the liquid-encapsulated Czochralski (LEC) method, gallium and arsenic or GaAs polycrystal is charged to a crucible, which is then placed in a pressure vessel. A seed crystal is dipped into the molten GaAs and seed is slowly pulled up with rotation to form a cylindrical single crystal, as shown in Figure 12. The molten raw materials are covered by molten B_2O_3, and the vessel is filled with a high-pressure inert gas (N_2 or He) to prevent vaporization. The crystal is pulled up through the molten B_2O_3 layer. If GaAs polycrystal is used as the raw material, the pressure of the inert gas can be as low as 10 bar (low-pressure LEC), but if a mixture of gallium and arsenic is used, the pressure should be > 70 bar to prevent vaporization of arsenic during the synthesis of GaAs (direct-synthesis LEC). The apparatus for low-pressure LEC is less expensive than that for direct-synthesis LEC, but the GaAs polycrystal must be made separately. Therefore the total manufacturing cost is higher in low-pressure LEC, and chances of increased contamination are greater. For these reasons, the high-pressure, direct-synthesis process is used predominantly today.

Figure 12. Liquid-encapsulated Czochralski method
a) GaAs crystal; b) Encapsulant, B_2O_3; c) GaAs melt; d) PBN crucible; e) Resistance heater; f) Heat shield; g) Chamber

As in the case of BG, various ideas have been tested to reduce the defect content of LEC wafers. In particular, EPDs of several hundreds per square centimeter can be attained by adding indium, though this has not been commercialized because of the high cost. Precise control of the stoichiometry, homogenization of the temperature distribution in the furnace, and thorough removal of impurities are the major countermeasures used to keep the EPD low.

At present, the standard level of EPD is (2–5)$\times 10^4$ cm^{-2}. Although this level is not fully satisfied, customers are more concerned about homogeneous EPD distribution in a wafer and throughout a crystal ingot.

Diameter control and diameter enlargement are also very important. However, apart from the case of silicon, automatic diameter control by optical methods is impossible in LEC because of the encapsulation by B_2O_3 and the slow heat response. This problem was solved by total computerization of the LEC process. Now most of the ingots are either3or4inches in diameter,and 5-inch wafers are in the developmental stage. Ingots of 3-inch diameter, 300 mm long (6 – 7 kg), are produced commercially. In addition, the successful development of 4-inch-diameter, 320-mm-long ingots (17 kg) has been reported [9].

For uses in microelectronics such as FETs or ICs, the single-crystal ingot must have semi-insulating properties, but since conventional processes use quartz crucibles, the ingot is always contaminated by silicon and becomes conductive. Therefore, the addition of small amounts of chromium (ca. 0.1 %) is required to compensate for silicon. However, because of the very low segregation coefficient of chromium (6×10^{-4}), its distribution in the crystal is inhomogeneous, and crystal properties vary within an ingot. The introduction of crucibles made from pyrolytic boron nitride (PBN) allowed semi-insulating crystals to be produced without adding chromium, which contributed greatly to the development of GaAs ICs. This method gives silicon concentrations of $< 5\times 10^{14}$ cm^{-3}, which are compensated by EL 2, an inherent defect in the crystal, which forms a deep-level donor. Semi-insulating undoped crystal can be produced without difficulty by using PBN crucibles.

To meet the requirement of GaAs IC devices, various modifications were tested to obtain large-diameter, round wafers with low defect content and high purity. Among these modifications, which included the use of an arsenic atmosphere, arsenic pressure control, and arsenic injection, magnet-application LEC (MLEC) is now used commercially. Application of a magnetic field reduces thermal convection and temperature variation in the furnace, and increases the viscosity of the melt, as in the case of silicon (→ Silicon). The surface of the crystal is smoother and has much less striation compared to crystals made by conventional LEC. A major reduction in the mean EPD level was not found, but the defects are distributed much more homogeneously within a wafer, which gives very uniform electrical properties. The MLEC apparatus is shown in Figure 13, and Table 2 lists the properties of semi-insulating wafers made by the MLEC process.

Table 2. Properties of semi-insulating GaAs polished wafers

Property	
Diameter, mm	100 ± 0.4
Thickness, µm	625 ± 10
Growth method	MLEC
Resistivity, $\Omega \cdot$ cm∗	$\geq 1\times 10^7$
Mobility, cm^2 V^{-1} s^{-1}	6000
Etch pit density, cm^{-2}	$\leq 7\times 10^4$

∗ after annealing at 850 °C for 20 min.

4.2.2.3. Comparison of the BG and LEC Methods

Both the BG and the LEC processes are used commercially, and each has its own characteristics. In general, BG wafers are used for optoelectronic devices such as LEDs and LDs, and LEC wafers are used for microwave and microelectronic devices, because the most important requirements are low defect concentration for the former, and large size and round shape for the latter.

Major characteristics of the BG method are as follows:

1) Automatic operation is easy, but unit production capacity is small and high man-power is required to prepare the equipment for startup
2) Dopant control is easy because no liquid encapsulation is applied
3) The control of temperature gradient is more moderate and precise than LEC (1 – 5 K/cm in BG, 30 K/cm in LEC); this gives low-EPD crystals
4) Round wafers cannot be made

The LEC method has the following features:

1) Large, round wafers can be made with minor cutting loss
2) Growth velocity is higher than in the BG method
3) By using a PBN crucible, the production of semi-insulating undoped wafers is possible

As mentioned above, each method has its own advantages and disadvantages, and both will coexist in future.

Single crystals of GaP have been used widely as the substrate for epitaxial production of visible-light LEDs. Because the vapor pressure of phosphorus is higher than that of arsenic, and the melting point of GaP is higher than that of GaAs, only the LEC method can be used, but the operating conditions are more severe than with GaAs. Wafers, 2 – 2.5-inches in diameter are made, and the EPD is ca. 2×10^5 cm^{-2}, which is higher than that of GaAs. A reduced EPD level is especially required of substrates for high-brightness green LEDs.

4.2.3. Wafer Processing

Single-crystal ingots are processed into wafers with the crystal orientation, shape, size, and surface properties required to meet specific uses. Basically, the methods of wafer processing are the same for BG wafers and LEC wafers except for the slicing direction due to the different crystal growth directions. Because device fabrication for high-speed ICs requires very fine, accurate pattern formation compared to discrete devices, the specifications for wafer processing, such as flatness and cleanliness, are much stricter. Here, the method for IC-grade wafers is described.

Figure 14 shows the process from an LEC ingot to mirror-surface wafers.

Figure 14. Block diagram of wafer processing

The ingot is ground to a fixed diameter, sliced by using an inner-edge saw, beveled to prevent chipping of the outer edge, and lapped to remove saw marks formed during slicing. The wafers are then etched by strong acid to remove the degraded layer and are processed to a mirror surface by polishing.

4.2.3.1. Slicing

Inner-edge saws are used exclusively for slicing, although wire saws have been tested. The flatness of the mirror wafer depends strongly on slicing operation parameters such as blade mounting, extent of blade bending, blade sharpness, and slicing speed. The orientation of the sliced wafer is inspected by X-ray diffraction or the light-figure method.

4.2.3.2. Lapping and Polishing

Lapping is the preliminary polishing process using fine grinding powder to remove saw marks and adjust wafer thickness. Group III – V materials tend to cleave easily, which causes scratches or cracks. Therefore, more careful attention must

be paid in selecting equipment and processing conditions than for silicon. Like final polishing, both single-side and double-side lapping are used, but the latter generally gives better accuracy and productivity.

Final polishing to give a mirror surface is conducted either by mechanical polishing with Al_2O_3 or SiO_2, by mechanochemical polishing with aqueous NaOCl, or by a combination of both. The mechanochemical method is used more widely and the composition of the polishing solution and the operating conditions are part of the important expertise of each manufacturer. In the case of single-side polishing in which wafers are mounted on a plate, the accuracy of the thickness depends strongly on the type of plate and the accuracy of wafer mounting, and washing with organic solvent is necessary to remove the mounting wax. The polished surface is easily washed, and its appearance is good. In the case of double-side polishing, in which no wax mounting is required, the accuracy of thickness is better and wafer washing is easy. During the collecting process, however, wafers tend to come in contact with each other, creating haze and scratches in the polished surface. Final polishing usually operates in a clean room of Class 1000 or better.

4.2.3.3. Surface Defects of the Polished Wafer

Surface defects include scratches, haze, dust, and pits, which are related to the inherent crystal defects. In addition, because a thin oxide layer is formed during wafer processing, polished wafers must usually be etched before device fabrication. So-called etching-free, fab-ready wafers, whose oxide layer is extremely thin, have been developed and commercialized in Japan.

In the case of silicon, wafer processing is fully automated, but for GaAs it is still in the partial automation stage because of the low production volume and high brittleness. To further improve the cleanliness of wafers, however, automation is very important.

Typical values of the surface properties of IC-grade GaAs polished wafers are listed in Table 3.

Table 3. Surface properties of GaAs wafers

Diameter, mm	100 ± 0.4	76.2 ± 0.4
Surface		
Polished side	damage-free finish	
Back	lapped and etched	
Native oxide layer	very thin	
Flatness		
Total thickness variation, µm	≤ 5	≤ 3
Nonlinear thickness variation, µm	≤ 5	≤ 3
Bow, µm	≤ 8	≤ 5

5. Epitaxy

Epitaxy is the growth of a crystal on another crystal along essentially the same crystal axis; this process is called epitaxial growth. The four epitaxial processes are

1) Liquid-phase epitaxy (LPE), in which the crystal grows on the substrate from a melt solution
2) Vapor-phase epitaxy (VPE), in which the elements or their volatile compounds are transported to the substrate, where they react to form a crystal
3) Organometallic VPE (OMVPE), which utilizes the thermal decomposition of organometallic compounds (OMCs)
4) Molecular beam epitaxy (MBE), in which VPE is conducted with a molecular beam generated under ultrahigh vacuum

Table 4. Comparison of expitaxial methods

Method	Advantages	Disadvantages
LPE	simple apparatus	inhomogeneous in thickness and composition
	high purity and high quality	rough surface
	constant stoichiometry	limitation in thickness
VPE	high productivity	limitation in thickness
	multilayer structure	toxicity of hydrides
	flat surface	
OMVPE	thin multilayer structure	purity of raw materials
	homogeneity and controllability of thickness	dependability of apparatus
	stoichiometry control	toxicity of OMCs and hydrides
		more expensive than LPE and VPE
MBE	best in thickness control	very expensive
	low-temperature operation	low productivity
	ultrathin multilayer structure	toxicity (in case of gas-source MBE)
	in situ observation	

The advantages and disadvantages of these four processes are summarized in Table 4.

The purpose of epitaxy is to make high-purity or mixed thin-layer crystals that cannot be made by bulk crystal growth. OMVPE and MBE are especially suitable for making ultra-thin multilayer structures that are used for high-performance devices.

Although epitaxy is used for silicon (→ Silicon, Chap. 4.2.5.), it is used much more widely for compound semiconductors.

5.1. Liquid-Phase Epitaxy (LPE)

LPE has long been used for compound semiconductors and magnetic garnets. NELSON first attemped to grow GaAs from gallium solution in 1963 [10]. Since then, many improvements have been made, and LPE is now used to make visible and infrared LEDs and LDs.

5.1.1. Principles and Apparatus

In LPE, a low-melting metal is used as the solvent and the supersaturated melt solution of the components is brought in contact with the substrate. The Ga – As phase diagram (Fig. 15) explains the principle of LPE [11]. The melt solution is saturated with arsenic at temperature T_1 and composition C_1. If this solution is cooled to temperture T_2, an amount of arsenic equivalent to $C_1 - C_2$ is supersaturated and the corresponding amount of GaAs is ready to deposit. GaAs LPE is carried out at ca. 800 °C, and the solution is supercooled by less than 10 °C ($T_1 - T_2 < 10$ °C), to avoid the formation of nuclei, and is brought in contact with the substrate.

The slide boat and dipping methods are both used commercially, the former more widely than the latter. The slide boat method is further divided into horizontal and vertical rotational types. Figure 16 shows the horizontal slide boat type. Raw materials and substrates are separately filled in a graphite boat, which is set in a quartz tube under a reducing atmosphere. The melt solution is then brought in contact with the substrate. In the case of GaAs, the GaAs solution is in the upper holder of the boat and the substrate is in the lower holder. The upper part of the boat moves, keeping contact with the lower holder, and when the melt solution moves over the substrate and comes in contact with it, supersaturated GaAs deposits and a crystal grows on the substrate. The movement of the boat is controlled automatically by a quartz rod. Vertical rotation LPE uses a cylindrical boat, and the melt solution and substrate are brought in contact by rotating either the upper or the lower holder.

Figure 15. Ga – As phase diagram

Figure 16. Slide boat LPE

The dipping process is shown in Figure 17. Melt solution is poured in the lower holder into which the substrate is dipped and an epitaxial layer grows. In this process, thermal deterioration of the substrate surface can be avoided by keeping the substrate at low temperature be-

fore starting growth. However, this process is not suitable for multilayer growth. It is used commercially for the LPE of GaP for green and red LEDs.

5.1.2. LPE of AlGaAs

Multilayer AlGaAs LPE on GaAs, with varying composition and dopant, is very important commercially for manufacturing high-brightness red LEDs. In LPE, melt solution and substrate are brought in contact at a fixed temperature, whereby supersaturated components deposit and crystal growth starts. Therefore, the composition of the melt solution that results in phase equilibrium at the fixed temperature must be found, so that ternary or quaternary compounds $Al_xGa_{1-x}As$, $Ga_xIn_{1-x}As_yP_{1-y}$, etc., can be grown with a required band gap energy, while the lattice match with the substrate is maintained.

Generally, simultaneous control of the lattice constant and the band gap energy is impossible, because only one parameter determines the composition. However, in the $Al_xGa_{1-x}As$ – GaAs system, since the lattice constants of GaAs and AlAs are very close (5.65325 versus 5.6605 at 27 °C), the band gap energy can be changed merely by changing the composition x and keeping the lattice matching.

LPE can make a very pure crystal layer, compared to other epitaxial processes, because high-purity gallium and GaAs are available, and only LPE can make a flat epitaxial layer over rough surfaces. However, it has inherent drawbacks such as uneven thickness caused by intermittent movement of the melt solution and a rough epitaxial surface due to residual melt on the surface. Therefore, LPE must coexist with other epitaxy process, depending on the device structure, productivity, and requirements for surface quality.

5.2. Vapor-Phase Epitaxy (VPE)

In a broad sense, OMVPE and MBE are also VPE processes. However, in this section only halogen-transportation VPE, which uses halides of group III elements as the transportation media, is discussed. The two halogen transportation VPE processes are (1) the chloride process, which uses $AsCl_3$, and (2) the hydride process which uses AsH_3 and PH_3.

The chloride process is simple, and the raw materials $AsCl_3$ and $GaCl_3$ are readily available in very high purity. It was used to make epitaxial wafers for FETs and ICs but has been largely replaced by the use of semi-insulating GaAs substrate made by the LEC method. In the hydride process, because commercially available HCl gas is not pure enough, making a very pure epitaxial layer is difficult. However, in the hydride process the amount of group III and V elements supplied can be controlled independently, and it is useful for growing mixed crystals. Commercially, the hydride process is used only to make $GaAs_xP_{1-x}$ mixed crystals for visible LEDs, for

which the content of arsenic and phosphorus must be controlled to change the wavelength of light emittance. The mechanism of crystal growth and the type of the reactor are similar for the two processes; here, the hydride process is described.

Principles and Apparatus. The apparatus for hydride VPE is shown in Figure 18. For the growth of $GaAs_xP_{1-x}$ epitaxial crystals, the vertical type is used almost exclusively because of its much better productivity.

Figure 18. Multiwafer VPE of $GaAs_{1-x}P_x$
a) Furnace; b) Ga reservoir; c) Rotating wafer holder; d) Reactor seal; e) Vent

Heated dry HCl gas is introduced to the gallium reservoir, the GaCl formed disproportionates to Ga and $GaCl_3$, and gallium is supplied to the substrate surface.

$$Ga + HCl \longrightarrow GaCl + 1/2\,H_2$$
$$3\,GaCl \longrightarrow GaCl_3 + Ga$$

The group V elements arsenic and phosphorus are supplied to the substrate surface by the thermal decomposition of AsH_3 and PH_3:

$$n\,AsH_3 \longrightarrow As_n + 3/2\,n\,H_2$$
$$m\,PH_3 \longrightarrow P_m + 3/2\,m\,H_2$$

Mixed crystal $GaAs_xP_{1-x}$ grows on the substrate surface, and the composition x can be changed by controlling the amount of arsenic and phosphorus. The higher x is, the longer is the wavelength of light emittance, as shown in Table 5.

Table 5. Composition of $GaAs_xP_{1-x}$ mixed crystal and wavelength of light emittance

Composition of epitaxial layer, $GaAs_{1-x}P_x$	Substrate	Typical wave-length, nm	Color
$GaAs_{0.90}P_{0.10}$	GaAs	780	IR
$GaAs_{0.80}P_{0.20}$	GaAs	740	IR
$GaAs_{0.70}P_{0.30}$	GaAs	700	IR
$GaAs_{0.61}P_{0.39}$	GaAs	660	red
$GaAs_{0.45}P_{0.55}$	GaP	650	red
$GaAs_{0.35}P_{0.65}$	GaP	630	orange
$GaAs_{0.25}P_{0.75}$	GaP	610	soft orange
$GaAs_{0.15}P_{0.85}$	GaP	590	yellow

In hydride VPE, excess amounts of gallium, arsenic, and phosphorus are supplied to the substrate, the lower the reaction temperature, the higher is the growth velocity. However, a reaction temperature of 750 – 800 °C is generally used because surface quality decreases with decreasing temperature. By using vertical type reactors, more than thirty 2 – 2.5-inch wafers can be charged in a reactor in $GaAs_xP_{1-x}$ epitaxy. Either sulfur or tellurium is used as n-type dopant, and the $p-n$ junction is made by diffusing zinc over the epitaxial layer. The dopant source is H_2S or diethyltellurium.

The brightness of LEDs made from $GaAs_xP_{1-x}$ epitaxy is very sensitive to small amounts of impurities. Therefore, care must be taken with raw material handling and operating conditions, including the material of the gas cylinders and the cylinder filling operation for AsH_3 and PH_3.

5.3. Organometallic Vapor-Phase Epitaxy (OMVPE)

Organometallic vapor-phase epitaxy is also known as MOCVD (metal organic chemical vapor deposition) or MOVPE (metal organic VPE).

LPE and VPE are suitable for making LEDs and FETs that have a simple layer structure and require high purity. With the development of various electronic and optoelectronic devices, such as high-speed and high-frequency HEMTs (high

electron mobility transistors), and quantum-well LDs, which have very complicated device structures, OMVPE has been of special interest, followed by MBE.

OMVPE has the following characteristics:

1) Formation of ultrathin multilayer structure with abrupt interfaces of the layers
2) Formation of multilayers including mixed crystals of precisely controlled composition
3) High uniformity and high productivity compared with MBE

In 1959, Reuhrwein referred to OMVPE, and the first research report was written in 1968 by Manasevit who succeeded in making a GaAs expitaxial layer on sapphire, germanium, and GaAs [12, 13]. In the 1970s, GaAs epitaxy was actively studied; with improvements in the purity of starting materials, the crystal properties and purity of the epitaxial layer have been greatly improved, and Gunn diode, Hall element, and microwave FETs have been reported. In 1977 the successful development of double hetero LD, multiquantum-well LD, and superlattice LD, quickly attracted attention to OMVPE.

5.3.1. Principles and Apparatus

Organometallic compounds and metal hydrides are used as raw materials that thermally decompose and supply metals. In the case of GaAs, trimethyl- or triethylgallium (TMG or TEG) is used as the gallium source and AsH_3 as the arsenic source. In group III – V or II – VI compound semiconductors, OMCs of group III or II elements and hydrides of group V or VI elements are thermally decomposed, and the resulting elements react on the substrate and deposit group III – V or II – VI compounds. The organometallic compounds should have the following properites:

1) Their vapor pressure should be ca. 1 torr (130 Pa) at room temperature
2) They decompose on heating
3) High-purity materials are available commercially
4) Thermal decomposition products neither prevent crystal growth nor contaminate the epitaxial layer

As shown in Figure 19, various steps occur in parallel and in series, and each step must be analyzed in detail to improve the quality of the epitaxial layer. However, this has not yet been achieved, because the mechanism of the thermal decomposition of OMCs is not clear, and no way exists to observe crystal growth directly. Even in the case of the TMG – AsH_3 system, which has been most widely studied, various model mechanisms have been proposed, such as (1) gas-phase reaction between TMG and AsH_3, (2) reaction between gallium and arsenic deposited on the substrate, and (3) formation of GaAs from TMG and AsH_3 adsorbed on the substrate.

Figure 19. Parallel and series steps of OMVPE

The OMVPE apparatus for $Ga_{1-x}Al_xAs$ is shown in Figure 20. This is a vertical reactor that operates at normal pressure. Raw materials are TMG, trimethylaluminum (TMA), and

Figure 20. Organometallic vapor-phase epitaxy (OMVPE)
TMG = trimethylgallium; TMA = trimethylaluminum; DEZ = diethylzinc
a) Mass flow controller; b) Purifier; c) Reactor

AsH_3, and the dopants are diethylzinc (DEZ; *p*-type) and H_2Se (*n*-type). AsH_3 and H_2Se are diluted by high-purity H_2 to 5 – 10 % and to several hundred parts per million, respectively, and then put in high-pressure cylinders.

The apparatus consists of three parts: gas inlet, reactor, and waste-gas treatment. In the gas-inlet system, stainless bubblers containing TMG, TMA, and DEZ are set in very precisely controlled thermostats. High-purity H_2, used as carrier gas, is purified further to remove H_2O and O_2, and is introduced to the bubblers to form a saturated vapor that is transported to the reactor through stainless steel piping. The flow rate of the raw materials must be controlled precisely, and to prevent contamination the piping should be leaktight and easily bakable for cleaning. The reactor part is made from quartz tube, and substrates held on a susceptor are heated by high-frequency radiation or by resistance heating. The saturated vapor supplied to the reactor furnace decomposes on the substrate and grows as *n*- or *p*-type $Ga_{1-x}Al_xAs$. In this case, the gas flow rate should be kept high enough to prevent a gas-phase reaction that curtails epitaxial growth. Gas is then sent to the waste-gas treatment to remove or burn residual gas or reaction products.

5.3.2. Operating Conditions

The reaction temperature is usually 650 – 700 °C, and in this temperature range, growth rate is proportional to the concentration and amount of TMG supplied. In OMVPE, growth rate is determined by the amount of group III elements supplied, because the amount of group V element is much higher. Therefore, in contrast to LPE and VPE, in which growth rate varies with time, in OMVPE the thickness of the layer can be controlled precisely by varying the concentration of TMG and the reaction time; high-quality, uniform epitaxial crystals can be obtained.

The growth of various mixed crystals such as InGaAs, InGaP, GaAsP, and GaAsSb has been attempted by using OMVPE. In these cases, composition control is very important, and to achieve it the concentration of group III atoms in the crystal should be proportional to that in the gas supplied.

The purity of the crystal layer has been increased greatly by improving raw material purity and by optimizing reaction conditions. The purity is now comparable to LPE, and GaAlAs – GaAs double hetero LD and HEMT devices are made by OMVPE as well as by MBE. For the growth of phosphorus-containing compounds such as InP and InGaAsP, OMVPE is superior to MBE, because the high vapor pressure of phos-

phorus makes vapor pressure control and waste-gas exhaust difficult in MBE.

5.4. Molecular Beam Epitaxy (MBE)

In MBE, the elements of the epitaxial layer are heated and vaporized under ultrahigh vacuum (1.3×10^{-8} Pa), and the resulting molecular beam is introduced to the substrate to grow the crystal. This is a highly specialized vacuum deposition technology. MBE was first reported by GUENTHER and was developed by CHO [14, 15]. Since then, this technology has been actively developed for device applications, mainly for group III – V compound semiconductors. The quality of the crystal has been improved with progress in raw material purification and ultrahigh-vacuum technology, and has reached a level comparable to LPE or VPE. MBE is now used to make thin layers not only of group III – V but also of group II – VI and single-element semiconductors, metals, and magnetic materials. Especially for group III – V compounds, as the control of doping and thickness at the atomic layer level became possible, the formation of superlattice structures by an abrupt heterojunction, control of dopant concentration at the atomic-layer level, and gradient doping have been used to make various high-performance devices.

5.4.1. Principles and Apparatus

The elements of the epitaxial layer are held in separate molecular beam cells and heated under ultrahigh vacuum. Molecules leaving the molecular beam cell go straight to the substrate, because under ultrahigh vacuum the mean free path of the molecule is much longer than the distance between the cell and the substrate holder. Therefore, the molecular beam has essentially no chance of being deflected by collision with other molecules. The standard MBE apparatus for group III – V compounds is shown in Figure 21.

During MBE growth, because of the high temperature of the cell and substrate, gases vaporize from these hot parts of the apparatus, making it difficult to maintain ultrahigh vacuum. To avoid the problem, a large liquid-nitrogen shroud and heat cutoff are used. A load – lock mechanism separates growth and substrate exchange areas with a gate valve, so that the ultrahigh vacuum of the growth area can be maintained when the substrate is exchanged.

By using ultrahigh-vacuum analytical methods such as Auger or electron-beam diffraction, both the growth speed and the appearance of the growing crystal surface can be observed. This is a unique advantage of MBE, which makes it useful for studying both growth mechanisms and manufacturing apparatus.

Since the cell must withstand $>1000\,^{\circ}$C, pyrolytic boron nitride is often used, and high-purity, high-melting metals such as tantalum are used as heater materials.

The growth rate of group III – V compounds is determined by the molecular beam strength of the group III elements, which depends on cell temperature. Beam strength is controlled precisely by measuring the intensity of the molecular beam and feeding it back to the temperature control system of the cell. The beam intensity is measured by using a quadrupole mass spectrometer or ion gauge. Generally, the growth rate is around one molecular layer per second.

In GaAs MBE, the substrate temperature is $500-600\,^{\circ}$C, and with excess arsenic, gallium is first adsorbed on the substrate, and then an equivalent amount of As reacts with gallium to form GaAs stoichiometrically. Excess arsenic desorbs from the substrate and is removed by the pump. In GaAlAs MBE, the cell temperatures of gallium and aluminum should be controlled separately for composition control.

5.4.2. Gas-Source MBE

In conventional solid-source MBE, the growth chamber must be opened to the atmosphere for refilling, and several days are required to reevacuate to 1.3×10^{-8} Pa. Because this greatly lowers productivity, processes that use a gas source such as organometallic compounds or metal hydrides were developed. The gases form molecular beams at $1.3\times10^{-2}-1.3\times\ 10^{-6}$ Pa, and material refilling can be obtained just by gas cylinder exchange without exposing the growth chamber to the atmosphere. In addition, gas-source MBE has the following advantages:

1) In solid-source MBE, controlling the composition of mixed crystals that contain more

Figure 21. Molecular beam epitaxy (metal and gas source)
a) Reflection high-energy electron diffraction (RHEED) pattern analysis system; b) Liquid-N_2 shroud; c) Substrate holder; d) Effusion cells; e) Gas cell (cracking); f) Pressure controller; g) Gas cylinder; h) RHEED (E-gun); i) Surface analysis system (AES, XPS)

than two group V elements is extremely difficult. In gas-source MBE, control of pressure and flow rate is easier.

2) Solid gallium sources tend to form oval defects on the crystal surface. Gas-source MBE can overcome this problem.
3) Gas-source allows crystal growth on the insulating layer to be avoided.

MBE is used widely for ultrathin multilayer epitaxy, especially for the multilayer GaAlAs structures of HEMTs and LDs. Among various epitaxial processes, MBE can make the thinnest layers, but the apparatus is very expensive and the growth rate is slow.

6. Characterization

The main factors that determine the quality of semiconductor crystals are the specific resitivity, the lifetime of charge carriers, and various kinds of crystal defects. Although cleanliness of the polished wafer surface is not an inherent property of the crystal, it is important in device manufacturing.

6.1. Specific Resistivity

Specific resistivity varies with the difference in the amount of dopants, which is related to the solid – liquid interface of semiconductor crystals and varies in the axial and radial directions of growth.

Specific resistivity is a function of the mobility and concentration of electrons and positive holes in the crystal as follows:

$$\varrho = 1/q\,(\mu_n\, n + \mu_p\, p)$$

where

ϱ = resistivity
q = charge of an electron

μ_n, μ_p = mobilities of electron and hole
n, p = concentrations of electron and hole

Resistivity is measured by two- and four-point probe measurements and by spreading resistance measurements (contact methods). The eddy current and microwave techniques are noncontact methods.

Four-point probe measurement is most widely used. Four probes make contact with the wafer in a straight line; a direct current is applied to the two outer probes; and the potential between the two inner probes is measured. The measured value is the average specific resistivity of the volume between the two probes.

In spreading resistance measurements, the diameter of the probe is very small (2 – 7 μm), and this method can measure the resistivity of extremely small parts of a wafer.

6.2. Lifetime of Charge Carriers

When a semiconductor crystal is excited by light or by application of a voltage, the concentration of electrons and positive holes generated decreases exponentially to restore thermal equilibrium. The lifetime is defined as the time constant of the damping curve. As discussed in Chapter 3, the lifetime of charge carriers is directly related to the properties and efficiency of semiconductor devices; it is therefore a very important parameter for the design and manufacture of devices.

The lifetime is measured by noncontact techniques such as the reflection waveguide method, which utilizes excitation by infrared for the generation of charge carriers and microwaves for the detection of output. In principle, the change in electrical or optical properties caused by excess charge carriers is measured as a function of time, and the lifetime is calculated from the time constant.

6.3. Crystal Defects

Three types of crystal defect exist: point, line, and two dimensional.

Point defects are empty lattice positions or interstitial atoms, and line defects are dislocations. When a surface in a crystal slips, the boundary between that surface and the standing surface is called dislocation. Dislocations cause strain in the crystal lattice and act as electron acceptors, which prevent carrier movement. Dislocation-free silicon crystals can be manufactured commercially, but GaAs crystals still have fairly large amounts of dislocations. Typical two-dimensional defects are multilayered defects and twin-crystal boundaries, which are often formed during crystal growth. The former is an irregularity of crystal lattice arrangement, and the latter is the boundary between crystals that have different growth directions.

Dislocation-free crystals exhibit microscopic defects known as swirls, which are observed as eddies on etching or as shallow pits by microscopy. Swirls are considered to be either aggregates of empty lattice sites or complexes of interstitial silicon atoms with oxygen.

During crystal growth, temperature distribution and growth velocity vary with crystal rotation, and the amount of dopant also varies periodically. These changes are observed as continuous stripes on selective etching or by X-ray topography, and are known as striations.

To evaluate the crystal structure and defects, X-ray topography, electron-beam diffraction, electron microscopy, and etching are used.

6.3.1. X-Ray Method

X-ray topography is most widely used for the characterization of crystal structure and lattice defects. If X-rays are applied to a crystal, they are scattered by each atom and interfere with each other, and the strongly scattered ray is found only in specific directions. In imperfect crystals, diffraction occurs not only at the lattice sites but also at the lattice defects. The picture of lattice defects is obtained by X-ray topography.

6.3.2. Electron-Beam Diffraction

To observe the surface structure and lattice defects of crystals, low- (up to several hundred volts) and high-energy (several thousand volts) electron-beam diffraction is used. The former is known as low-energy electron diffraction (LEED) and the latter as reflection high-energy electron diffraction (RHEED).

Both can be used to analyze the surface structure of crystals qualitatively and quantitatively. Because RHEED utilizes a higher accelerating voltage, a much cleaner image can be obtained, and it allows in situ monitoring of crystal growth in MBE.

6.3.3. Electron Microscopy

To observe crystal defects and crystal microstructure, transmission electron microscopy (TEM) is used. In TEM, an electron beam of uniform current density is applied to a thin-layer probe, and the transmitted or diffracted electron beam is analyzed. The accelerated voltage of the electron beam is usually 100 – 400 kV or 1 – 3 MV in the case of ultrahigh-voltage TEM.

6.3.4. Etching

The observation of lattice defects by etching is the most popular method of crystal evaluation, because etching speed depends on growth direction, type of conduction, type of dopant, lattice defects, and surface structure of the crystal. Various etching solutions are used (Table 6). Etching processes involve an oxidation reaction, followed by decomposition and removal of the oxide.

6.4. Contamination of the Wafer Surface

About 70 % of the problems in the manufacturing of large-scale integrated circuits (LSIs) are a result of particles adhering to the wafer surface, which leads to defects in the shape and appearance of the pattern. Adhering particles cause pattern defects during dry etching and ion implantation because either the particles act as masking materials, or atoms of the particles diffuse into the substrate. Therefore, particle formation must be checked and reduced in each manufacturing stage by measuring and controlling the condition of the wafer surface.

To inspect the particles on the surface, laser-beam diffraction is widely used. Laser beams are applied to the wafer surface, and the resulting diffraction or scattering of the beam caused by particles is received by a collecting lens. Scanning electron microscopy (SEM) is used to observe the shape of particles.

To analyze elements on the surface, electron probe microanalysis and auger electron spectroscopy are used. The former measures specific X-rays generated when a very fine electron beam scans the probe, and the latter measures the electron energy generated by the auger state when an electron beam of 3 – 10 keV is applied.

These methods can be used to analyze inorganic materials. For organic materials, other methods such as infrared microspectroscopy, fluorescence analysis, and Raman spectroscopy are used.

7. Semiconductor Devices

As shown in Figure 22, two main types of semiconductor device can be found: discrete devices and integrated circuits. Discrete devices are unit components that have specific electronic functions such as rectification, amplification, oscillation, and photoelectric conversion. ICs are small structural units in which discrete devices, such as resistors or condensers, are mounted on a silicon semiconductor substrate and inseparably bonded. Although discrete devices have their own important applications for broad uses, with the development of IC manufacturing technology, major advances in miniaturization and cost reduction have been achieved.

ICs have many advantages over discrete devices, including small size, low weight, lower consumption of electricity, high speed, and high reliability. Because the IC manufacturing process is capital intensive and well suited to mass production, the cost per unit function becomes much cheaper with increasing degree of integration.

However, with the diversification of usage, multigrade small-volume production for specific uses became more important. To meet this requirement, application specific ICs (ASICs), such as gate arrays, were developed. ASICs consist of standardized unit circuits whose specific function can be varied by changing the bonding between them.

Table 6. Characteristics of etching solutions

Solution	Composition		Etching velocity, µm/min	Remarks
Dash	HF	$10\,cm^3$	0.1	slow
	HNO_3	$30\,cm^3$		suitable for microdefects
	CH_3COOH	$120\,cm^3$		
Sirtl	HF	$100\,cm^3$	1	depends on growth direction
	Cr_2O_3	50 g		
	H_2O	$100\,cm^3$

Figure 22. Classification of semiconductor devices

7.1. Brief Description of Various Devices

7.1.1. Diodes

Diode is the general term for devices that have two electrodes. A wide variety of diodes exist including the rectifier diode, voltage reference diode, varactor diode, Gunn diode, impatt diode, and tunnel diode. The three types of rectifier diode are the $p-n$ junction, the Schottky junction, and the pin diode. The pin diode has a high-resistance depletion layer between a $p-n$ junction. The pin diode is used as a high-voltage rectifier because a high reverse voltage can be obtained.

The voltage-reference diode keeps the voltage of both terminals constant by utilizing the breakdown phenomenon; that is, the electric current abruptly increases at a specific reverse voltage.

The varactor is a variable-capacitance diode used for frequency tuning. It utilizes the fact that the depletion-layer capacitance of a $p-n$ or Schottky junction varies with changing voltage.

Impact avalanche transit time (IMPATT) diodes, which are used for the oscillation and amplification of microwaves, utilize negative resistance. This diode has an n^+-n-p junction, and when biased at breakdown, this structure forms negative resistance due to the avalanche effect and transit time effect of carriers (Gunn diode, Schottky diode, tunnel diode, see Chap. 3). The IMPATT diode has a depletion layer adjacent to the junction which makes the transit time of the carriers between the electrodes very short, enabling them to pass through the depletion layer.

7.1.2. Transistors

Transistors consists of two $p-n$ junctions (i.e., three terminals). Various electric actions – amplification, oscillation, rectification, etc. – occur among these three terminals by the action of electrons or positive holes. The three terminals are the emitter (E), collector (C), and base (B). In the $n-p-n$ transistor, as shown in Figure 23, the emitter and collector are n-type and the base is p-type. In the base only a few charge carriers exist as minority carriers, and when forward biased, charge carriers are injected into the base from the emitter and then absorbed in the collector by reverse biasing. The electron flow from emitter to collector is controlled by the base potential with no power expenditure because the base is much thinner than the emitter and collector.

Figure 23. Junction transistor

The transistor is used as an amplifier: the current injected into the base at low voltage flows through a high reverse bias, resulting in a higher voltage (voltage or power amplification).

This mechanism is very similar to the vacuum tube. In a vacuum tube, electrons are emitted from the cathode when it is heated to $> 1000\,°C$ and these electrons reach a positively biased plate. This electron flow is controlled by a grid potential. Since the grid is negatively biased and is a grating, electrons can pass through it easily without loss of power.

Both the transistor and the vacuum tube have an electron supply source and collector, and electron flow is controlled by an electrode that absorbs practically no electrons. The major difference is the electron source. In the vacuum tube, because electrons are emitted from metals such as tungsten and must cross a potential barrier $>1\,eV$, the cathode must be heated to $>1000\,°C$. On the other hand, in the transistor, release of electrons or positive holes by donor or acceptor requires only 30 meV of activation energy, which can be achieved at room temperature. This is the reason the transistor has totally replaced the vacuum tube.

There are two types of junction transistor: bipolar transistors and field-effect transistors (FETs). Whereas bipolar transistors utilize both electrons and positive holes, FETs use either electrons or holes. The bipolar transistor was first developed by Brattain and Bardeen as a point-contact transistor in 1947; then Schockley developed the junction type based on his theory of the $p-n$ junction. The bipolar transistor is suitable for obtaining high current and high speed, but is structurally unsuited to high integration.

FETs are used for amplification, switching, and other applications. In the FET, the current from the source (emitter) to drain (collector) is controlled by the voltage impressed to a gate terminal (base) as shown in Figure 24. The gate is a metal electrode separated from the semiconductor surface by an insulating layer on the substrate. SiO_2 is most widely used as the insulating layer, and this type of FET is called a metal oxide semiconductor FET (MOSFET). MOSFETs are basic units of large-scale ICs, especially memories. GaAs FETs that use a semi-insulating GaAs substrate instead of an SiO_2 insulating layer show good performance in microwave amplification and very high-speed digital ICs. The HEMT is a heterojunction FET, which has a two-dimensional electron – gas interlayer that gives higher electron mobility and lower noise at microwave frequencies than conventional GaAs FETs.

Figure 24. Structure of a MOSFET

7.1.3. Integrated Circuits

Integrated circuits are miniature structures in which many circuit elements are inseparably bonded on or within a substrate.

The original purpose of the development of ICs was simply miniaturization and weight reduction. However, during development, many other advantages were observed and pursued.

The first of these is cost reduction, achieved mainly by the introduction of photoetching, which utilizes photographic technology. When finely patterned negatives are applied to millions of transistors, their arrangement and wiring can be made by repetition of the treatment. The higher the degree of integration, the more effective is this method. Furthermore, because IC packaging is performed as a totality, rather than for each transistor, the number of bonding points and the consumption of packaging materials can be reduced; this also contributes greatly to cost reduction.

Second, the reliability of performance has increased considerably. Most failures originate at bonding points, but in ICs, the number of bonding points has decreased because many components are integrated in a silicon wafer. In addition, reduction in the number of manufacturing steps is also advantageous for performance reliability.

Third, performance itself has also improved. The smaller the transistor, the shorter is the wiring, and the higher the speed. Higher integration becomes possible.

The concept of ICs was proposed shortly after the invention of the transistor, and the invention of the metal oxide semiconductor (MOS) planar transistor by FAIRCHILD provided the basis for LSI, because its structure was suitable for high degrees of integration.

7.1.3.1. Memory

Since the introduction of the 1 kbit MOS memory by Intel in 1971, semiconductor memories have been used widely in many electronic appliances. The three types of MOS memories, pMOS, nMOS, and cMOS, use positive holes, electrons, and a combination of these as carriers, respectively. The pMOS was commercialized first because the separation of the individual elements is easy. Then, with increasing integration, nMOS replaced pMOS because of its higher speed. When the integration reached 1 Mbit, cMOS became the main technology because of its low electric consumption.

Memory is classified as random-access memory (RAM) and read-only memory (ROM). RAM can both write and read, whereas ROM can only be read. RAM is divided into DRAM (dynamic) and SRAM (static) memory. DRAM needs refreshing to maintain memory, but SRAM does not.

The memory action of DRAM is maintained by the electric charge stored in the capacitor, but the charge is lost by leakage current. Therefore, refreshing is needed. Because DRAM consists of only one transistor and one capacitor, it is the simplest semiconductor device. Memory capactiy has been increasing by a factor of four every three years. Capacity has now reached 4 Mbit and will reach 1 Gbit by the end of the 20th century. The basis of this progress is the development of fine processing technology. The progress in device fabrication is shown in Table 7. The wiring line width must be decreased by a factor of 0.6, when integration increase by a factor of four.

SRAM consists of six circuit elements to maintain memory stability, and the integration is about one generation behind DRAM.

DRAM is most widely used for all types of computer and control apparatus, whereas SRAM is used for the main memory of supercomputers and the cache memory of office computers and minicomputers, which especially require high speed.

The two types of read-only memory are mask ROM and programmable ROM. Mask ROM cannot eliminate the memory once written, whereas programmable ROM can rewrite. Both types of ROM are widely used for program storage of word processors, personal computers, workstations, televisions, etc.

7.1.3.2. Logic Circuits

Logic circuits are basic circuits for computer and digital control. Logic circuits judge an input signal or a combination of plural input signals and decide the level of output signals. In the early stages, bipolar logic circuits were standard. However, with the development of small

Table 7. Progress of device fabrication

Integration (DRAM)	256 kbit	1 Mbit	4 Mbit	16 Mbit	64 Mbit

Tolerable diameter of particles, μm	0.2	0.1	0.05	≤ 0.05	≤ 0.05
Wafer diameter used, inch	4	5	6	8	8 – 10

portable appliances, MOS logic circuits are also being used. Bipolar logic circuits can treat signals about ten times faster than MOS logic. However, the power consumption of MOS logic circuits is lower than that of bipolar circuits.

Bipolar logic circuits consist of a transistor, a diode, and a resistor. They are used mainly in computer components, data transmission, and various industrial controls such as instrument control, numerical control, and process control, which require very rapid speed.

Because MOS logic circuits consists of only MOS FETs, a high degree of integration can be achieved fairly easily at low cost and small size. MOS logic circuits were first used for pocket calculators and then for microcomputers and video game machines, etc. They have made a major contribution to the miniaturization of these devices.

Applications for supercomputers, instrumentation, and military uses require ultrahigh speed and low power consumption. In these cases, GaAs logic ICs are gradually replacing bipolar logic circuits, especially in the United States.

7.1.3.3. Analog Integrated Circuits

Analog ICs, also known as linear ICs, process analog signals. A wide variety of analog ICs are used for both industrial and consumer purposes. Industrial uses include general-purpose devices such as amplifiers and voltage regulators, and specific uses such as motor regulators, temperature regulators, and smoke detectors. Specific consumer uses are in TVs, radios, tape recorders, cameras, air conditioners, and refrigerators. The integration of analog ICs is generally much lower than digital ICs, but has now reached 400 elements per square millimeter, and more than 10 000 elements are integrated in a single chip. Some of these process both analog and digital signals. For instance, analog – digital systems are used for digital audio tape (DAT) and digital TV, and their applications are broadening. In industrial uses, higher speed and higher frequency are being pursued for image processing.

7.1.4. Hybrid Integrated Circuits

In hybrid ICs, conductors, condensers, and resistors are made as films on the insulator, and semiconductor devices are mounted on it. The major features of hybrid ICs are

1) High precision and high reliability
2) Suitable for high-power, high-voltage, and high-frequency circuits
3) Small size but sufficiently high function
4) Easy to apply to custom uses
5) Low development expenses and short delivery time

To manufacture hybrid ICs, the circuit patterns of the resistor, conductor, and condensers are printed on the ceramic insulator with paste and then heat treated (thick-film hybrid ICs). If thin film is required, the circuit pattern is made by a combination of lithography with deposition or sputtering (thin-film hybrid ICs).

7.1.5. Application-Specific Integrated Circuits (ASICs)

Nowadays, as customer requirements diversify, manufacturers must respond with small-volume, multigrade production. In ASICs, standardized circuit blocks for signal treatment are combined with the specific circuit blocks of each customer by using computer-aided design (CAD). This system enables the requirements of each specific customer to be met in a short delivery time. With the increasing variety of equipment functions, the trend toward ASICs is becoming stronger.

Gate arrays and standard cells are the two most important ASIC products. The main part of the gate array is a standard logic circuit, but the wiring is different for each user. A standard cell is a block that consists of a logic gate memory or a central processing unit, etc., and each user can assemble custom LSIs by combining these cells.

Since gate arrays entered the market in 1977, their speed, integration, and functions have been greatly improved. Now many kinds of gate array are used in the industrial and consumer markets. Bipolar gate arrays are used mainly for computers, communications, instruments, and image processing which require very rapid information processing. The cMOS gate arrays consume less power than bipolar arrays, and high integration can be achieved easily. Thus cMOS gate arrays with 3000 – 5000 gates are used widely for both consumer and industrial applications, and they contribute to miniaturization of equipment, cost reduction, and improvement of reliability. The development of very fine processing technology has allowed an array with $>10^5$ gates to be produced. Bi- cMOS gate arrays, which are a combination of bipolar and cMOS gate arrays, have been introduced for special uses.

Because standard cells require trial production for each user, longer and more expensive development is required compared to gate arrays. However, standard cells offer greater design freedom, and more highly functional products can be made. Now standard cells with several hundred thousand gates are manufactured commercially.

7.2. Wafer Fabrication

In the manufacturing of ICs, major advances have been made toward higher integration, finer patterning, and more precise processing. On the other hand, the huge investment costs for sophisticated equipment and the R & D expenses required to meet the above requirements have resulted in increased manufacturing costs. Therefore, manufacturers are making efforts aimed at process rationalization, yield improvement, automation, manpower reduction, and standardization.

The basic flow sheet of wafer processing is shown in Figure 25:

Figure 25. Wafer fabrication process

1) The polished wafer is heated to form an SiO_2 insulating layer on the surface.
2) The SiO_2 layer is coated with photoresist (a photosensitive resin) and prebaked. The circuit pattern is formed by using a photomask on the prebaked surface for mask matching.
3) The wafer is then exposed to UV light, for example, and developed to remove exposed or unexposed photoresist, depending on the type of resist.
4) The wafer is washed and dried and after postbaking, the SiO_2 layer is removed by wet or dry etching.
5) Dopants are then implanted by high-temperature diffusion or ion implantation in areas of the wafer surface where SiO_2 has been removed. (Steps 1 to 5 are repeated, depending on the device structure.)

6) Metals are deposited on the wafer for the formation of wiring and electrodes.
7) The electrical properties of the pattern are inspected by probing after the underside of the wafer has been polished.

The IC elements thus fabricated are divided into individual pieces by scribing and then sent to the assembly process, which includes die bonding, wire bonding, packaging, sorting, and screening.

7.2.1. Formation of Insulation Layer

The establishment of insulation layer technology contributed greatly to the development of the MOS transistor because the quality of the wafer surface on the outside can be maintained as well as the inside of the wafer. Various kinds of insulation layers [SiO_2, Si_3N_4, borophosphosilicate glass (BPSG), etc.] are formed by high-temperature oxidation or chemical vapor deposition (CVD) for gate insulation, capacitor insulation, interlayer wiring insulation, element separation, passivating layers, etc.

SiO_2 layers made by high-temperature oxidation have been widely used as insulation layers for gates and capacitors. SiO_2 layers are formed by reaction with atmospheric or high-pressure dry or wet oxygen at 700 – 1200 °C. Batch diffusion furnaces or lamp furnaces are used.

To form interlayer insulation for multilayer wiring, CVD is used. CVD is classified into low-pressure, atmospheric, and plasma CVD. For SiO_2 and Si_3N_4, the insulating layer can be made at temperatures as low as 300 °C by using the plasma CVD method. In this case, silane is generally used, but tetraethoxysilane gives layers with better flatness.

To form a smoother coated layer, phosphosilicate glass (PSG) or BPSG is applied by using atmospheric CVD. The latter can be deposited at lower temperature.

The method of local oxidation of silicon (LOCOS) has been used for the separation of electrical elements, and this technology is the basis of the development of MOSLSI. LOCOS consists of the following steps:

1) An SiO_2 layer is formed by high-temperature oxidation
2) An Si_3N_4 masking is applied to allow selective oxidation for element separation
3) Dopant is introduced into the separated areas
4) A thick SiO_2 layer is formed by oxidizing the separate areas

To improve and stabilize the electrical properties of the semiconductor surface, a passivation layer is formed to prevent contamination of and damage to the surface. Two methods are used for this purpose. One is to make a protective layer of Si_3N_4; the other is so-called gettering, in which contaminants such as sodium ions are absorbed or deactivated by the PSG layer. Sometimes both processes are combined.

Other purposes of passivation are (1) protection of the SiO_2 – Si interface, (2) protection of aluminum wiring, and (3) protection of electrical contact pads after wire bonding.

7.2.2. Lithography

Lithography (see also → Imaging Technology, Chap. 4.3.) is a technology for pattern formation derived from photography. To form the pattern of a device or circuit, the semiconductor substrate is coated with photoresist and is exposed, developed, and etched through a photomask. This technology is an important basis for achieving high integration of semiconductor devices, and finer patterning must be pursued for higher integration. Table 7 shows the relationship among the degree of integration, minimum line width, chip area of a DRAM, and the exposure technology.

Depending on the source of light, the technology of lithography is called photolithography, electron-beam lithography, ion-beam lithography, etc. Photolithography is most widely used. The equipment used in lithography is called a stepper, which employs g-line light (wavelength 436 nm) from a high-pressure mercury lamp. The stepper exposes the photomask negatives through a lens by a step-and-repeat process because the field is too small to image the entire wafer.

A further increase in integration requires improvements in resolution, depth of focus, field size, alignment, etc. This means using shorter-wavelength light. The first step is to use the ultraviolet i-line (365 nm) for 16-Mbit DRAMs; then excimer lasers of KrF (248 nm) and ArF

(193 nm) should be used for higher integration. For the next generation, IC exposure by electron beam or soft X-rays is being studied for >1-Gbit integration. The wavelengths of these sources are sufficiently short, but the equipment itself is still in the developmental stage.

7.2.3. Doping

Impurity doping is a basic technology of device fabrication. Thermal diffusion, ion implantation, plasma doping, and laser doping are all used for impurity doping. Among these, thermal diffusion and ion implantation are the most popular and are described here.

7.2.3.1. Thermal Diffusion

In thermal diffusion, the diffusion source – either gas (PH_3, AsH_3, B_2H_6), liquid ($POCl_3$, BBr_3), or solid ($Al_2(PO_3)_3$, BN, B_2O_3) – is heated to ca. 1000 °C. The resulting dopant oxides adhere to the surface of the substrate and are reduced to their elements by the substrate. Dopant atoms then diffuse into the substrate. This process is known as two-step diffusion.

The other process is solid-state diffusion. In this case, a dopant-containing layer is formed on the substrate surface by spin application or CVD and then heated.

The productivity of thermal diffusion is very high, and the controllability in the high-concentration diffusion range is excellent because the maximum surface concentration is determined by thermal equilibrium. However, in the low-concentration diffusion range the controllability is unsatisfactory. Therefore, the thermal diffusion process is generally used when the requirements for concentration control are not very strict.

7.2.3.2. Ion Implantation

The principle of ion implantation was invented in the 1950s by Western Electric or Nishizawa and was applied in the 1970s to the threshold control of the MOS transistor at low dopant concentrations. This technology has now replaced thermal diffusion in many cases.

In ion implantation, a gas or vapor that contains the dopant element is converted to the plasma state; the ions in the plasma are accelerated by a high-energy field and implanted in the semiconductor substrate. This technology has various advantages over thermal diffusion:

1) Since the amount of dopant implanted is controlled by the integrated value of the beam current, the accuracy is very high
2) Ions are implanted very uniformly, and the reproducibility is good
3) Because the implantation mechanism can be modeled theoretically, the distribution of implanted ions can be estimated
4) Dopants can be implanted through a surface layer

Nowadays, ion implantation is applicable to almost all LSI device fabrication. Because the collision of ions with atoms in the substrate results in many defects on crystal lattices, however, the damaged crystallinity must be restored by heat treatment (annealing).

As shown in Table 8, the equipment is classified into four types depending on the strength of the electric current applied. With the development of submicron devices, the trend is toward high current and high energy.

Table 8. Methods of ion implantation

Beam	Acceleration and voltage		
	10–60 keV	60–200 keV	400–1000 keV
Low (10–100 μA)			High-energy machine
Middle (100 μA–2 mA)	Middle-current machine	Middle-current machine	High-energy machine
High (2–30 mA)	High-current machine	High-current machine	
Ultrahigh (ca. 100 mA)			Oxygen implantation (developmental)

7.2.4. Etching

Etching is applied for either surface treatment or selective etching during lithography. The two types of etching are wet and dry. In wet etching, liquid chemicals such as hydrofluoric acid are

used, whereas dry etching utilizes the chemical or physical action of highly reactive gases.

Wet etching has been used for many years because it causes no damage to the substrate, and the throughput and selectivity are high. However, because the etchant solution penetrates into the boundary between photoresist and substrate, the accuracy of device fabrication deteriorates. Therefore, wet processing is not applicable to the fine patterning of highly integrated circuits.

The processing accuracy of dry etching is much better than that of wet etching, and automation is easy. For these reasons, dry etching is replacing wet etching despite low throughput and damage to the substrate surface.

Plasma etching, reactive etching, reactive-ion etching, and photoetching processes are used, depending on the material, shape, and structure of the devices. Dry etching processes are listed in Table 9.

Table 9. Dry etching processes

Mode	Mechanism	Source of reaction	Reactive gas
Chemical	plasma	radical	CF_4, $CF_4 + O_2$
	photo (UV, laser)	active ion	Cl_2, $Cl_2 + SF_6 + NF_3$, SF_6
Physicochemical	reactive ion	active ion	CCl_4, CF_4, $SiCl_4$
	reactive ion beam	active ion	SF_6, CHF_3
Physical	sputtering	inactive ion	Ar
	ion beam	inactive ion	Ar

7.2.5. Washing

Semiconductor surfaces are very sensitive, and device characteristics are affected not only by impurities in the bulk of the semiconductor but also by impurities adhering to the surface. These surface effects increase with increasing fineness of pattern. Therefore, washing technology is very important to obtain expected device characteristics with high yield.

Surface impurities include particles, metals, organic substances, oxide layer, etc., which are removed by wet or dry washing. With increasing integration and finer patterning of devices, the requirements for surface cleanliness are becoming more stringent. The wet washing process is used mainly because it can be applied to most impurities, including fine particles.

7.2.6. Wiring Technology

To increase the integration of ICs, the area used for wiring on the chip must be decreased. However, reduction of wiring-pattern width is limited by the current-carrying capacity and the wiring resistance. To solve this problem, multilayer wiring technology was developed for bipolar LSIs and MOSLSIs in the early 1970s. As wiring materials, aluminum and polysilicides, such as $MoSi_x$ or WSi_x, are used.

8. Supporting Industries

8.1. Building

The most important issues in building specifications for semiconductor materials and device manufacturing are cleanliness and absence of vibration. The former is discussed in the next section, but basically the building should be designed to avoid contamination by recycling air from the utility or maintenance zone where various chemicals and gases are treated. As for vibration, the base and surrounding conditions such as roads and railways should be studied carefully. Also, the building structure should prevent the propagation of vibration from equipment installed in the building. For equipment that is especially sensitive to vibration a local antivibration system can be installed.

8.2. Clean Room

With the increasing density of integration, the effect of contamination on quality, manufacturing yield, and product reliability has become extremely critical because of the finer patterning. Therefore, the production of ultraclean wafers is a core technology of semiconductor device fabrication. Of course, the same considerations apply to wafer processing (polishing, washing, inspection, and packaging).

The primary factors in yield drop are pattern defects caused by particles adhering to the wafer or photomask. Determining the minimum particle size that causes pattern defects is very complicated, but empirically a particle size one-tenth

of the minimum line width (design rule) must be considered for removal from the standpoint of yield and reliability. In the case of memories, when the integration is increased by a factor of 4, the chip area increases by 40 – 50 %. This increase in area requires a further reduction of the remaining finer particles per unit area. Particles come from the environment, equipment, and materials (including gases and chemicals), but the major source of particles is the operators. Therefore, a strong trend exists toward automated operation.

Figure 26. Schematic of a laminar-flow clean room
a) Primary filter; b) Middle filter; c) Intake fan; d) Final filter; e) Exhaust fan; f) Recycled air

Table 10. U.S. Federal Standard of Cleanliness∗

Class	Particle size, µm∗∗				
	0.1	0.2	0.3	0.5	5.0
1	35	7.5	3	1	NS
10	350	75	30	10	NS
100	NS	750	300	100	NS
1 000	NS	NS	NS	1 000	7
10 000	NS	NS	NS	10 000	70
100 000	NS	NS	NS	100 000	700

∗ Number shown means tolerable upper limit of particles of each size per cubic foot (1 $Ft^3 \approx 28$ L).
∗∗ NS = not specified.

The basis of clean room specification is the U.S. Federal Standard 209 D (Table 10). However, more recent LSI processes necessitate a more stringent specification of 1 – 10 particles of > 0.1-µm diameter per cubic foot (super clean room level). Clean rooms use either the total laminar flow or partial laminar flow system; the former is generally used in advanced clean room technology. As shown in Figure 26, outer air is supplied to the clean room through primary, secondary, and final filters. The final filter, installed in the ceiling of the room, is specified by 0.1-µm particle size and is known as a high-efficiency particular air filter (HEPA filter) or ultralow-penetration air filter (ULPA filter). The volume of air supplied is equivalent to that which replaces the room air at a rate of 70 – 500 times per hour. Dust particles generated in the room are taken out with the recycled air and removed by filters. About two-thirds of the total air is recycled.

Figure 27. Modern ultraclean water system

8.3. Ultraclean Water

Because ultraclean water is generally used at the final stage of processing, its quality strongly affects the cleanliness of wafers. As shown in Table 11, specifications are becoming increasingly rigorous. Major items to be checked are number and size of particles, ions, and live bacteria. In addition, removal of total organic carbon (TOC) and dissolved oxygen is required to prevent formation of an oxide layer.

Particle specifiction is based on past experience. Metal ions such as chromium and iron must be limited to the 0.01-ppb level. Live bacteria cause shape defects, and the elements phosphorus, sodium, and potassium can diffuse from them to the inside of wafer on heat treatmet to form abnormal conducting areas or to cause performance to deteriorate. The TOC is a nutrient for live bacteria and causes defects in the oxide layer of the gate. Dissolved oxygen helps increase live bacteria, and the thickness of the natural oxide layer formed by water rinsing depends on the dissolved oxygen concentration.

An ultraclean water system consists of a primary clean-water system, subsystems, and a wastewater recovery system. In the primary system, industrial or well water is treated by filtration or multifunctional ion exchange to remove particles, ions, organic compounds, live bacteria, and dissolved oxygen. The purified water is sent to subsystems where it is treated by UV light, anion polishers, and an ultrafilter to remove TOC and other microimpurities. To lower manufacturing costs and volume consumption, high-efficiency wastewater recovery systems must be used.

An ultraclean water system for 16-Mbit DRAMs is shown in Figure 27. This system utilizes the following technologies and achieves the target levels listed in Table 11:

1) Removal of fine particles by a double-skin ultrafilter module
2) Removal of TOC, dissolved salt, and SiO_2 by two-stage low-pressure reverse osmosis
3) Use of low-elution ion-exchange resins to remove TOC
4) Sterilization by high-energy UV light
5) Sterilization by hot water (80 – 90 °C) using heat-resistant poly(vinylidene fluoride) piping
6) Lowering of dissolved oxygen concentration by nitrogen purging and membrane degassing

Stains or water marks caused by water droplets remaining on the wafer and electrostatic breakdown can be avoided by using high-pressure water jets. On-line continuous measurements of fine particles and TOC are available. With increasing wafer diameter, the consumption of ultraclean water is increasing, and the improvement of space efficiency, the development of recycling systems or of fully closed systems, and cost reduction are important issues for ultraclean water.

8.4. Gases

Various gases are used in LSI fabrication:

1) Conventional industrial gases such as H_2, N_2, O_2: These are used widely in many steps, and the consumption volume is high. LSI plants usually have on-site production or storage facilities, and these gases are supplied by pipeline.
2) Highly toxic and explosive gases such as SiH_4, AsH_3, PH_3, and B_2H_6 for epitaxy and dopant diffusion.
3) Halogenated gases or chlorofluorocarbon gases for etching (HCl, Cl_2, CCl_4, $SiCl_4$, CF_4, etc.).

These gases are classified in Table 12 from the standpoint of application.

Table 12. Major gases used in semiconductor process

Process	Gases
Epitaxy and CVD	SiH_4, AsH_3, PH_3, $(C_2H_5)_2Te$, $(C_2H_5)_2Zn$, O_2, N_2O, NH_3
Surface oxidation	O_2, N_2, H_2, H_2O
Diffusion and ion implantation	AsH_3, PH_3, B_2H_6

With the development of finer patterning and higher-performance devices, raw materials of very high purity, including gases, are always requested. In many cases, however, the analytical methods have not yet been established, and the relationship between gas purity and device performance is not clear. To obtain high-purity gases at the point of use, attention must be paid not only to the manufacturing of the gases but

Table 11. Quality requirement for ultraclean water

	Integration			
	1 Mbit	4 Mbit	16 Mbit	Currently achieved

Size, µm	0.1	0.08 – 0.1	0.05	0.07
Number, L^{-1}	20 000 (max.)	10 000	10 000	1
Number of live bacteria, L^{-1}	50 (max.)	50	10	1
Total organic carbon, ppb	50 (max.)	30	10	1
Dissolved oxygen, ppb	100 (max.)	50	50	10

also to transportation, storage, piping, etc. In particular, the cylinder materials, including valves, O-rings, and packing, and the method of filling are very important.

Environmental issues relating to gases are discussed in Chapter 9.

8.5. Other Chemicals

8.5.1. Quartz

Quartz glass is widely used in semiconductor manufacturing processes as boats, crucibles, piping, bell jars, etc., for the following reasons:

1) Very high heat resistance and low coefficient of thermal expansion
2) Chemically stable except toward HF and H_3PO_4 (>300 °C) and stable to molten metals
3) Good electrical insulation and low dielectric loss factor regardless of frequency

However, when quartz glass is used as a boat or crucible in contact with molten materials, possible contamination must be carefully checked in advance. In the case of silicon single-crystal pulling, oxygen and metal impurities seriously affect the quality of the silicon wafer and the electrical properties of devices. Silicon permeation from quartz affects the conductivity of GaAs.

Major impurities in quartz are aluminum (5 – 30 ppm), boron (0.1 – 0.3 ppm), iron, sodium, potassium (0.1 – 2 ppm); copper (0.05 – 0.1 ppm); and 1 – 200 ppm of water. Different impurities are critical, depending on the processes in which quartz is used.

For the process tube used to supply gases for doping, CVD, etc. in LSI fabrication, heavy and alkali metals must be removed. For this purpose, natural quartz powder is melted by an oxyhydrogen flame, and copper and alkali metals are removed by evaporation.

For the diffusion process, quartz tubes are made by electrical melting in vacuum furnaces. This quartz has a higher content of metal impurities, but it is resistant to high-temperature flexure because it contains almost no water.

Synthetic quartz tube made from $SiCl_4$ by oxidative melting in an oxyhydrogen flame contains very small amounts of metallic impurities, but the water content is high. This is used as crucibles for making high-purity single crystals.

8.5.2. Pyrolytic Boron Nitride

Pyrolytic boron nitride (PBN) is made from BCl_3 and NH_3 by vacuum chemical vapor deposition. The reaction product BN deposits on a graphite mold, which is subsequently removed. PBN crucibles are used for making semi-insulating GaAs by LEC (see Chap. 4). The characteristics of PBN are as follows:

1) Very high purity because the CVD process is used
2) Very inert to chemicals and molten metals
3) Highly heat resistant (in an inert atmosphere it is resistant up to 3000 °C and has better thermal shock resistance than quartz)
4) Very expensive but can be used repeatedly

PBN is also used for MBE crucibles. For the production of silicon single crystals, PBN is not used because the electrical properties are very

sensitive to boron contamination. Even in GaAs LEC, boron contamination remains a problem.

8.5.3. Graphite

High-purity graphite is an indispensable material for the semiconductor industry and is used as a susceptor, heater, and thermal insulator for single-crystal and epitaxial growth of silicon, GaAs, and others.

Manufacturing high-purity graphite is a time-consuming process, and quality control is very difficult. Coke and tar pitch are mixed and molded by extrusion or by a rubber press, preheated at ca. 900 °C, and then graphitized at ca. 2800 °C. Preheating and graphitization are repeated for purification. This process takes several months. At this stage, the product still contains about 0.5 % impurities (Al, V, Si, B, SiC, etc.). For further purification, graphite is heated with chlorine or fluorine, which do not react with it, at 2500 – 2800 °C. A typical analysis of purified graphite is shown in Table 13.

Table 13. Typical analysis of purified graphite

Constituents	Content, ppm (max.)
Ash	10
B	0.1
Fe	0.1
Cu	0.01
K	0.01
Na	0.01
Al	0.02
Si	2

With the increase of single-crystal diameter, strength improvement of graphite became very important, and extrusion molding was replaced by the use of rubber presses, which can make more uniform and stronger products.

For the group III – V materials GaAs and GaP, the thermal condition of LEC is more severe than with silicon and high pressure is also applied. Therefore, the requirements for graphite quality are more rigorous.

8.5.4. Others

As shown in Table 14, many kinds of chemicals are used in lithography, etching, washing, and other steps. Particle content and metal impurities strongly affect the quality of devices. Currently the quality of electronic-grade (EL) chemicals basically satisfies most users.

Table 14. Chemicals used in device fabrication

Washing	
Particles	$NH_4OH - H_2O_2 - H_2O$, Choline $- H_2O_2 - H_2O$
Metals	$H_2SO_4 - H_2O_2$, $HCl - H_2O_2 - H_2O$, $HNO_3 - HF - H_2O$
Organics	$H_2SO_4 - H_2O_2$, $NH_4OH - H_2O_2 - H_2O$
Natural oxide layer	$HF - H_2O$, $HF - NH_4F - H_2O$
Drying	isopropanol
Lithography	tetramethylammonium hydroxide for development butyl acetate for rinsing $H_2SO_4 - H_2O$, phenol for peeling off
Etching	
of SiO_2	HF, etc.
of Si	$HF - HNO_3 - CH_3COOH$
of Si_3N_4	H_3PO_4
of Al	$H_3PO_4 - HNO_3 - CH_3COOH$

Electronic-grade chemicals require further purification (e.g., by filtration, distillation, and ion exchange).

The particle content should be less than $20\,mL^{-1}$ of 0.1-µm particles for the production of 16-Mbit DRAM. Typical particle contents are, however, higher than this, and the particle content increases during transport. Chemical producers and LSI manufacturers are cooperating to solve this problem.

With regard to metal impurities, the requirements are also becoming much more rigorous as integration increases. In the case of 16-Mbit DRAM, $<0.1 - 1$ ppm is specified depending on the metal. Most commercially available chemicals (H_2O_2, NH_4OH, H_2SO_4, HCl, and HF) meet this requirement.

9. Environmental Aspects

In the electronics industry, many toxic and flammable substances are used from crystal growth to device fabrication. In 1985, NIOSH registered 182 substances in this area, and their number is increasing and changing with technological progress. In addition, most of these substances are discharged in various states (gas mixtures, liquids, fine particles, sludge, etc.), which makes treatment before they are released to the environment very complicated.

9.1. Gases

Many kinds of gases are used in epitaxial growth, CVD, formation of SiO_2 layers, doping, and dry etching, as shown in Table 12.

Among them, the hydrides (SiH_4, B_2H_6, PH_3, and AsH_3) are very toxic, highly explosive, and inflammable. When they leak, they tend to combust spontaneously. Hence special safety measures such as installation of a gas-leak detector, thorough ventilation, waste-gas treatment, emergency counterplans, and periodic inspections should be followed. The same attention should be paid to H_2 and NH_3.

When mixed with flammable gases, O_2, N_2O, and NF_3 accelerate explosion. The use of NF_3 as a dry etchant is increasing. With inert gases such as N_2 and argon the danger of an unbreathable atmosphere must also be considered.

9.2. Liquid Chemicals

Acid, alkali, and salts are used mainly in wet etching and washing processes. The consumption of HF and mixed acid (mixture of nitric and sulfuric acid) is very high. Both result in serious burns, and HF readily penetrates the skin and destroys tissues. Toxic gases are sometimes evolved during acid washing. Organic solvents are used in deoiling and photoresist processes.

These chemicals must be used in the specified closed station under a ventilation system to prevent the exposure of operators and the contamination of clean rooms.

9.3. Metals

Metals such as aluminum, antimony, arsenic, lead, zinc, titanium, and nickel are used in vacuum deposition or ion implantation. They are all extremely pure, and consumption is low. For arsenic and lead, special attention must be paid to the exposure of workers, for example, in the cleaning of GaAs crystal pullers.

9.4. Chlorofluorocarbons (CFCs)

In June 1990, to avoid destruction of the ozone layer in the stratosphere, the decision was made internationally to ban the use of certain CFCs (CFC 11, 12, 113, 114, 115) and 1,1,1-trichlorethane, for example, by the year 2000. In addition, a ban on hydrochlorofluorocarbons (HCFCs) was also discussed. Since then, most electronic companies are aiming to essentially stop the use of these CFCs by 1995.

In the IC manufacturing process, CFC 113 and 1,1,1-trichloroethane are used in washing, and other CFCs are used in dry etching. Consumption of the first two is especially high. Besides destruction of the ozone layer, another issue is that CFCs are carcinogenic, leak into the soil, and contaminate ground water. In response to the CFC regulations, both short- and long-range actions are being taken. The following are the short-range actions:

1) Use of closed systems to avoid the evaporation of CFCs
2) Reduction of consumption by improving equipment and operation
3) Recovery and recycle of used CFCs

Medium- or long-range counter measures include the development of more environmentally friendly CFCs such as HCFC 134 a and HCFC 225. World CFC producers have established an international program for alternative fluorochlorocarbon toxicity (PAFT) to confirm the safety of these products before commercialization.

Other developments are the replacement of CFCs by alcohol or water for washing, or even conversion to a washingless process. In alcohol washing, ethanol, isopropanol, and 5-fluoropropanol, for example, are being studied. Water washing includes the use of emulsifiers and terpenes besides pure water. Replacement of CFCs by other substances is still in a developmental stage and requires substantial changes in the entire manufacturing process to meet customers' quality requirements.

Attempts are being made to replace other dangerous chemicals by safer ones; the following are examples of such trials:

1) Use of tetraethoxysilane instead of silane in plasma CVD for formation of the SiO_2 layer
2) Formation of the SiO_2 layer at lower temperature by using liquid chemicals such as tetraalkoxysilanes

3) Use of arsenic metal or organoarsenic and phosphorous compounds to replace AsH_3 and PH_3 in OMVPE and ion implantation
4) Replacement of cellosolves by safer chemicals in the photoresist process

10. Economics

Silicon. Currently (1991), five Japanese (Shin-etsu, Mitsubishi Materials, Osaka Titanium, Komatsu Electronic Metals, and Toshiba Ceramics) and two German (Hüls and Wacker Chemitronic) companies are manufacturing silicon wafers; Texas Instruments, Motorola, and AT & T in the United States are minor producers who use their wafers captively. The production share of Japanese companies is ca. 70 %. Most of these seven companies have global production systems in the United States, Europe, and Asia, or in two of these three areas.

Worldwide production statistics for single-crystal silicon ingot are not available, but according to the Japan Society of Newer Metals, estimated Japanese production volumes in 1991 and 1992 were 2210 and 2300 t, respectively. Based on these figures, the estimate of worldwide production volume in 1991 and 1992 is 3200 and 3300 – 3400 t. On the other hand, Dataquest estimated worldwide consumption of silicon wafers in 1991 and 1992 at 2133 and 2237 million square inches, which corresponds to <200 t in weight. This means that the yield of polished silicon wafers from single-crystal ingots is very low. Production of silicon wafers in 1991 amounted to $\$ 2.27 \times 10^9$.

Wafers are becoming larger with increasing chip size. Now, 6-inch wafers are the most widely used, and 4- or 5-inch wafers are limited to specialty uses. Eight-inch wafers were expected to be used for the commercial production of 4-Mbit DRAM. However, their introduction has been delayed because of the slow market for 4-Mbit DRAM.

Compound Semiconductors. Worldwide statistics for compound semiconductors are not available. However, except for minor captive production by Hewlett – Packard (United States) and Siemens (Germany), about 90 – 95 % are produced in Japan, including epitaxial wafers. According to the Japan Association of Compound Semiconductor Manufacturers, Japanese wafer production amounted to $\$ 159 \times 10^6$ in 1989 and $\$ 186 \times 10^6$ in 1990. Therefore, worldwide production in 1990 was ca. $\$ 200 \times 10^6$, which is less than 10 % of silicon wafer production. The unit price of compound semiconductor wafers is several times higher than silicon, and the percentage of the more expensive epitaxial wafer is high. Based on these, the production volume of compound semiconductors is only 1 – 2 % that of silicon.

Both visible and infrared LEDs are made exclusively from compound semiconductors, GaAs, GaP, and InP. GaAs is becoming established in amplifiers in high-frequency areas such as satellite broadcasting and communications, and devices that require low consumption of electricity such as computer cache memories, although large-volume consumption is not expected.

In LED production, 2 – 2.5-inch epitaxial wafers are used; 3- and 4-inch substrates are used in other applications. Device manufacturers are interested in using 5-inch wafers or larger, but this would necessitate a large investment by both wafer and device producers, and is not economically justifiable at this stage.

Major Japanese wafer makers are as follows:

1) Epitaxial wafers for LEDs: Mitsubishi Kasei, Showa Denko, Shin-etsu
2) Substrates for microelectronic uses: Mitsubishi Kasei, Sumitomo Electric, Hitachi Cable

Semiconductor Devices. Semiconductor devices are now used not only in computers but also in almost all industries relating to everyday life such as communications, displays, home appliances, automotives, aeroplanes, instrumentation, and automation.

According to the forecast of the World Semiconductor Trade Statistics (WSTS), worldwide consumption is estimated as shown in Table 15. Production and consumption of semiconductor devices began in the United States and was dominant there until the middle of the 1980s. Since then, Japan has become the largest producer. In the 1990s market shares were Japan 40 %, United States 30 %, Europe 17 %, and remainder 13 %. In the 1990s, the share of Asian countries

except Japan increased because of the rapid expansion of Korean companies and the transferral of their plants to the Asian area by device fabricators in Japan, the United States, and Europe.

Table 15. Forecast of worldwide semiconductor consumption by WSTS ($ 10^9)

Country	1991	1992	1993	1994
United States	15.6	18.0	20.1	21.7
Japan	21.5	24.5	27.1	29.2
Europe	10.2	11.1	12.4	13.4
Others	8.3	10.0	11.6	12.8
Total	55.5	63.6	71.2	77.2

The top ten device manufacturers in 1991 are as follows, according to Dataquest (J = Japan, U = United States, E = Europe): (1) NEC (J); (2) Toshiba (J); (3) Hitachi (J); (4) Intel (U); (5) Motorola (U); (6) Fujitsu (J); (7) Texas Instruments (U); (8) Mitsubishi Electric (J); (9) Matsushita Electronic (J); (10) Philips (E).

1. Introduction

Ever since the Romans began wearing sandals, shoe care has been practiced as a way of softening, protecting, and extending the duration of footwear use. Animal fats were applied to leather footwear to replenish natural fatty oils lost as a consequence of exposure to the elements. As the chemistry of leather treatment progressed, providing corrected-grain, chrome-tanned, finished footwear, the sophistication of shoe dressings advanced concomitantly. Modern polishes consist of a complex mixture of waxes, silicones, and polymers dissolved in appropriate solvents. This delicate balance of materials provides a protective coating that is easily applied, adheres strongly, and is easily buffed to the desired gloss. The selection of solvents is driven by chemical properties of the gloss components, and ranges from water to volatile organic solvents.

It is interesting to note that approximately the same shoe-care formulae are used in different countries irrespective of location, with the exception that higher melting waxes are employed in tropical climates. However, the *type* of shoe dressing preferred does reflect certain cultural differences, as exemplified by the fact that liquids are most common in Mexico, southern Europe, and the Far East, whereas paste polishes have a greater share of the market in North America, Africa, and Australia, and in northern Europe there is heavier use of shoe cream.

2. Footwear Materials and Processes

Most dress shoes utilize fully corrected-grain leather for the upper section, the part that requires polishing. The first stage in the conversion of animal skin into leather is tannage, which is the impregnation of chromium or tannic acid salts into the hide (→ Leather). Tanning the leather prevents resident microorganisms from putrefying the hide upon rewetting, a process that causes irreversible damage. A typical shoe upper utilizes rough tanned ox hide, such as zebu or brahma. The hide is first *chrome tanned*, whereby chromium sulfate is introduced to fix the hide; that is, chromium ion complexes with carboxyl groups in the hide proteins. Basic conditions favor the formation of large chromium complexes, permitting cross-linkage between adjacent protein molecules. This cross-linking reaction in turn provides a stabilizing effect against excessive drying and the otherwise detrimental action of hot water. The hide is then dyed and softened using a fat liquour (an oil-in-water emulsion used to introduce oil into the hide).

Finally, texture is imparted to the leather by buffing the grain with fine sandpaper (e.g., #220 paper) to make it smoother and more uniform. Generally, the grain of the leather requires additional finishing to ensure an acceptable "break", manifested as creases in the shoe as it flexes during walking. The finishing of a fine, fully corrected-grain leather requires the application of several finishing coats prior to a high-gloss

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a23_575

top coat such as nitrocellulose. Typical materials involved in achieving a conventional corrected-grain finish by a four-step process are listed in Table 1.

Table 1. Compositions of the individual coats applied in a four-step leather finishing process ([9], p. 417)

Component	Content, wt %			
	Step 1	Step 2	Step 3	Step 4
Impregnating polyurethane polymer dispersion	20.0			
Water	70.0	52.5	50.0	50.0
Solvent penetrator (2-butanone)	10.0			
Pigment paste		20.0	20.0	
Wax emulsion		2.5	2.5	
Casein emulsion			7.5	
Acrylate polymer dispersion		25.0	20.0	
Nitrocellulose emulsion				50.0

In the scheme outlined in Table 1, a solvent penetrator (2-butanone) is used to promote the adherance of a polyurethane polymer, which serves as a bottom base coat. This is usually followed by an acrylate polymer dispersion to provide gloss and bind pigment to the substrate. In the third step, more polymer solution is applied with casein to improve adhesion and/or a wax base for additional gloss. A nitrocellulose top coat is applied last to ensure a brilliant protective coating.

Leather for the upper parts of casual shoes is treated less extensively, providing a more natural "leather" look. Such shoe uppers are typically manufactured from silicone- or oil-tanned leathers, which are subjected to fewer finishing steps and often remain undyed and relatively porous. Special shoe- care products are required to maintain the resulting natural-looking finish.

Man-made plastic-type shoe materials were introduced a number of years ago, but they still play a only minor role in shoe construction. Thus, the descriptions of formula attributes that follow are predicated on leather as the upper shoe construction material.

3. Solvent-Based Shoe Polish

Cream and paste shoe polishes have been utilized since the early 1800s to protect, repair scuffs, and provide shine. Three fundamental groups of materials contribute to the formula properties: solvents, wax blends, and dye dispersions. A balanced formula is required to produce a shoe polish that possesses such mandatory attributes as high solvent-binding capacity, good heat stability, ease of application, rapid buffing, scuff coverage, high spectral reflectance, and satisfactory paste-surface physical characteristics.

3.1. Composition

Wax Blend. The most critical decisions during formulary development center around the selection of wax components, wax ratios, and total wax concentration. After volatilization of the solvent, the coating properties that remain are a direct reflection of interactions between the wax components and the dye system.

A typical solvent paste polish must contain 20 – 40 % wax components to produce a paste with satisfactory hardness as measured by a precision penetrometer. Care must be taken to balance the relative percentages of high-melting waxes versus low-melting paraffin-type materials in order to achieve the desired surface characteristics and paste firmness. For instance, if low-melting waxes were to be used exclusively in a formulation with only 20 % wax solids, the resulting paste would be unacceptably soft, with poor solvent-binding properties. ("Solvent-binding" is the phenomenon that prevents a paste from rapidly becoming a dry solid.) Most shoe-polish formulae contain a mixture of microcrystalline natural ester waxes, oxidized montan waxes, and a paraffin base (→ Waxes). Selection of the wax components requires a consideration of solvent-binding capacity, gloss value, and hardness index. Synthetic waxes like the non-emulsifiable polyethylenes and Fisher – Tropsch wax can be substituted to some extent to produce equivalent results.

To maintain satisfactory paste attributes, a good balance must be achieved between solvent-binding capacity and gloss value. Paraffin is a major wax ingredient, but it displays both poor gloss and poor solvent-binding properties. Carnauba, candelilla, refined montan, and certain oxidized montan ester waxes from BASF and Hoechst improve the gloss properties markedly. Montan, ozokerite, and Hoechst Wax O, OM,

or OP also improve the solvent binding capacities of paraffins. Table 2 summarizes the general solvent-binding and gloss properties of various waxes based on their contributions to paste-polish characteristics.

Table 2. Characteristic properties of various waxes

Wax	Solvent binding	Gloss
Paraffin	poor	poor
Microcrystalline	moderate	poor
Carnauba	moderate	excellent
Hoechst Wax O	good	fair
Hoechst Wax OM	poor	good
Hoechst Wax OP	good	good
Hoechst Wax S	good	fair
Hoechst Wax F	poor	fair
Montan (refined)	good	good
Ozokerite	good	poor
Candelilla	poor to moderate	very good

Solvent. Essentially, a solvent acts to solubilize wax components in a form that permits the development of a relatively uniform, thin film coating on the leather substrate. Upon evaporation, a thin wax film can be buffed to a desirable gloss. Many different solvents have been utilized in shoe polish [e.g., turpentine, mineral spirits, V.M. & P. ("Varnish Makers and Painters") naphtha, and Stoddard solvent (ASTM D-484-52)], both singly and in combination. Generally, turpentine is considered the solvent of choice due to its relatively high kauri-butanol value, its volatility, and a characteristic "shoe-polish" odor. However, the high cost of turpentine has led to its being largely replaced by mineral spirits in most water-free pastes. The physicochemical properties of mineral spirits (boiling range, kauri-butanol value, evaporation rate, and density) compare favorably to those of turpentine. Nevertheless, the replacement of turpentine with mineral spirits must be undertaken carefully to ensure retention of sufficient aromatic content, since this affects how wax recrystallizes during manufacture. An excellent compromise is a solvent blend of turpentine and mineral spirits with a 10 – 50 wt % turpentine concentration.

Dye Dispersions. To provide appropriate depth of gloss, a basic solvent dye (e.g., Nigrosine Solvent Black #2) must be predispersed in a carrier prior to its incorporation into a wax blend or liquid molten paste. Basic nigrosine dye (→ Azine Dyes, Chap. 2.2.4.) must be neutralized with a fatty acid to make it soluble in the solvent/wax mixture. Normally, a nigrosine base is reacted with either oleic or stearic acid. Nigrosine stearate has the advantage of not lowering the melting point of the wax blend. Being a solid, however, it has the disadvantage of imposing extra processing steps. Rhodamine (→ Fluorescent Dyes, Chap. 4.) and chrysoidine (→ Azo Dyes, Chap. 5.1.1.) dye materials are treated in a similar fashion, leading to cordovan, oxblood, and brown polishes. Dyes supplied originally in an oil-soluble form can be incorporated directly into the solvent, molten wax, or paste.

Table 3. Representative shoe-polish formulations

Chemical component	Relative content, wt %					
Crude carnauba wax		2.0		1.5	5.5	2.0
Montan wax (refined)	2.5			2.0	3.0	2.5
Wax OP ∗	3.5		5.0	1.5		
Wax O ∗		6.5		6.0		3.0

Formulae. The number of potential permutations of wax blends is large. Table 3 provides several representative formulae.

3.2. Production

Manufacture of a water-free shoe paste requires a minimum of two vessels to produce molten paste prior to filling. A steam- or electrically-jacketed vessel with good temperature control is essential for melting the wax and ensuring homogeneity. Typically, the paraffin wax is

melted first to provide a heat sink for the subsequent processing of higher-melting waxes. The stearin – dye mixture is added last due to its thermal lability and susceptibility to charring. The temperature required to obtain a completely soluble wax blend is typically 100 – 130 °C depending upon the nature of the wax materials.

The wax blend is then added slowly over 5 – 10 min to the solvent (turpentine or mineral spirits). The solvent temperature must be maintained at ca. 50 – 60 °C during this paste-formation step. Depending on the size of the vessel, agitation can be provided by a propeller mixer for most polishes. The mixture should be agitated for 15 – 30 min and then filled at a pouring temperature of 40 – 45 °C.

For more efficient manufacture, development of the proper consistency for a polish can be facilitated by passing the filled containers through a cooling tunnel maintained at 5 – 10 °C. Some formulations need not be cooled on an accelerated basis due to the nature of their wax constituents and the paste characteristics that develop naturally. Suitable precautions are required during solvent handling due to the potential for combustion of the mixture.

3.3. Quality Specifications

The resultant paste should present a hard, smooth, glossy surface appearance in the can. Unbalanced formulation or poor chemical processing may lead to dye incrustation, solvent exudation, bloom, or cake contraction, each of which constitutes a critical defect from the standpoint of consumer response.

Dye incrustation and bloom both result from poor binding of the dye – stearin component, causing preferential migration and recrystallization of the stearin at the surface.

Solvent exudation occurs with a wax blend lacking adequate solvent-binding capacity. Pastes rich in paraffinic wax often suffer from this phenomenon. *Cake contraction* is caused by shrinkage of the paste mass in the can, resulting in contraction from the side walls. This is caused by a formulation with an excessive hard-wax content, and leads to what is known in the trade as a "rattler". Such contraction may render the product totally unsalable within a few weeks or months.

4. Emulsion Shoe Creams

Shoe creams are generally much softer in consistency than paste polishes. They are offered in a wide range of colors for application on fashion shoes, and provide excellent staining of scuff marks with perfect matching of the original shoe color. Shoe cream formulae may or may not contain solvent, although most do include some solvent to improve wax solubilization and ease of application.

4.1. Composition

Wax/Solvent Emulsification. The formulator of a shoe cream must select waxes that are both emulsifiable and capable of displaying high gloss properties and high solvent-binding capacity. Examples include carnauba, beeswax, montan, and various oxidized montan waxes (e.g., Hoechst waxes E, S, KSL, and LP). The simplest emulsions are formed in situ by adding ammonia or morpholine together with a fatty acid like oleic or stearic acid. Fugitive emulsifiers like ammonia are excellent for use in coatings, since they evaporate after application and thus do not affect the coating properties. Other surface-active agents can be utilized as well to decrease the interfacial surface tension and thereby facilitate emulsion formation. Hydrophilic – lipophilic balance (HLB) values provide the simplest guide to preparing an oil-in-water or water-in-oil emulsion, since these reflect the hydrophobicity of the surfactant molecules (→ Emulsions, Chap. 2.8., → Emulsions). Extensive literature is available from ICI Americas on the use in this context of the polysorbate esters known commercially as Spans and Tweens. The more hydrophilic the system, the more likely it is to form water-in-oil emulsions (e.g., HLB 4 – 6). In a complex emulsion, stabilization requires a combination system such as that formed in situ between morpholine stearate and a Tween/Span mixture.

Dye Systems. Shoe creams must provide excellent scuff coverage, since this is a primary consideration from the consumer standpoint. This effect is achieved with a combination of

oil-soluble and acid dyes. Acid dyes display particularly effective staining characteristics. In some systems, pigment dispersions are introduced concomitantly due to acid-dye instability with respect to the alkaline materials required to form many emulsions.

Formulae. Table 4 provides examples of emulsion shoe-cream formulations. Such formulations result in an oil-in-water emulsion in which the emulsifier, morpholine stearate, is formed in situ. The use of turpentine as solvent permits incorporation of an excellent wax blend, providing a cream with moderate gloss and excellent staining characteristics. The actual concentration of colorant depends upon the desired color. Carnauba, Wax E, and Wax KSL form especially stable emulsions. Emulsions can also be formed with a Tween/Span combination or a single-component surfactant if so desired, although residual surfactant slightly reduces water-resistance properties.

Table 4. Representative shoe-cream formulations

Component	Relative content, wt %			
Carnauba wax	4.0		7.5	3.0
Montan wax (refined)	2.0		2.5	1.5
Wax E ∗		4.5	3.0	4.0
Wax KSL and/or LP ∗		3.5		2.5
Paraffin wax	8.0	6.0	5.0	7.0
Morpholine	1.5	1.5	1.5	1.5
Stearin	0.5	0.5	0.5	0.5
Turpentine	32.0	32.0	30.0	30.0
Water	50.0	50.0	48.0	48.0
Color mixture	2.0	2.0	2.0	2.0

4.2. Production

One steam- and water-jacketed vessel is required to heat the wax phase and form an emulsion at ca. 85 °C. After the wax phase has reached this temperature the solvent should be added, followed by the water phase while mixing. Then the pigment – dye dispersions are added to the emulsion kettle and the mixture is agitated for 15 min to ensure homogeneity. Finally, morpholine is incorporated to produce a stable emulsion. Mixing with an appropriate propeller mixer should result in an emulsion within 5 – 10 min. Cold or ambient water is then introduced into the jacket to cool the shoe cream. Alternatively, it may be allowed to cool passively. The shoe cream can be poured into jars at 45 – 52 °C; alternatively, it can be cooled to ambient temperature and then dispensed as a cream into tubes or glass jars.

4.3. Quality Specifications

An acceptable shoe cream should have a smooth, creamy appearance in the jar or tube, matching the color represented on the label. Emulsion stability is critical, as evidenced by the absence of free solvent or water in the container. Emulsion stability can easily be tested either by accelerated high-temperature storage (100 – 125 °C) or successive freeze – thaw cycles to establish emulsion integrity. Poorly formulated creams will fail such a test, leading to distinct phase separations. Moreover, dye systems require careful material selection to prevent dye interactions that would lead to color drift.

5. Liquid Polishes

Liquid (or "dry-bright") shoe polishes have been used for many years as a way of providing a quick, convenient shine with high pigment concentrations capable of hiding scuffs (e.g., on white nurses' shoes and children's footwear). A thin, flexible, polymeric coating is laid down on the shoe surface in such a way that it requires no buffing. Generally, these formulations contain three principal functional components: a polymeric binder, a wax emulsion, and a pigment dispersion. Drying may entail a combination of solvent evaporation and polymer cross-linking.

5.1. Composition

Polymeric Binder. Selection of the correct polymer is critical to formulating an acceptable dry-bright liquid shoe dressing. The polymer must be capable of binding the heavy pigment load, and it must also provide gloss, adhere to the substrate, and form a flexible film at room temperature. To produce an acceptable film coating the polymer must have a glass-transition temperature well below ambient temperature.

Styrene – acrylic copolymers, acrylate copolymers, and polyurethane polymers have all been used successfully in liquid shoe polishes. Styrene – acrylic copolymers are especially common in dry-bright emulsions because the styrene ensures good gloss properties while the acrylate contributes flexibility. Polyurethanes, while providing excellent gloss and flexibility, are not favored because they are difficult to remove from the leather substrate.

Pigment Dispersion. Most dry-brights are formulated with a high pigment concentration (5 – 30 wt %) for the purpose of covering the leather surface with a film of dispersed pigments. White shoe polishes require an extremely high pigment concentration to provide thorough coverage. Common pigments include yellows and oranges based on lead chromate, browns from iron oxides, and blues of synthetic organic origin (e.g., Acid Blue #9). White shoe polish always contains titanium dioxide (TiO_2) (→ Pigments, Inorganic, Chap. 2.1.). Anatase-grade TiO_2 was formerly used exclusively due to its favorable particle size and its slightly bluish tint, but the more modern chloride manufacturing process leads to an acceptable rutile-grade TiO_2 with excellent coverage.

Formulae. The core formula for a dry-bright shoe polish consists of a polyethylene wax emulsion, polymer, and colorant. Adhesion is provided by a *resin solution* (e.g., an aqueous ammoniacal solution of rosin-modified maleic resin), sometimes supplemented by a casein – borax solution, which significantly improves film adhesion. The resin solution plays an important role as a leveling agent. In its absence the polymer may pool on the surface. The resin helps fill the holes between wax – polymer molecules, thereby contributing to a smooth film. Crazing or cracking results from the brittleness inherent in most hard, high-gloss polymers. To prevent crazing, *plasticizers* may also be incorporated [e.g., tributoxyethyl phosphate (KP-140) or dibutyl phthalate]. Finally, a *glycol* is usually added to provide freeze – thaw stability by depressing the freezing point.

The following are simple examples of formulae for a dry-bright shoe polish and a corresponding wax emulsion (figures denote weight percentage):

Dry-bright shoe-polish:	
Wax emulsion	15
Polymer dispersion (40 % solids)	25
Resin solution (15 % solids)	18
Tributoxyethyl phosphate	2
Ethylene glycol	2
Casein solution (15 % solids)	10
Pigment dispersion	10
Morpholine	2
Water	16
Wax emulsion:	
Polyethylene	15
Oleic acid	2
Morpholine	2
Water	81

5.2. Production

Mild heating (45 °C) facilitates manufacture of a dry-bright emulsion using simple propeller mixing assuming the pigments are supplied in predispersed form. In the case of titanium dioxide, high-speed dispersion equipment is required. Generally, the resins and casein solution, as well as the polymer, are added first, and these are emulsified by the addition of morpholine or some other base. Polyethylene wax emulsion, plasticizer, etc., are then added, followed by the pigment dispersion. After all components have been combined the batch is mixed for 15 – 30 min prior to filling into bottles.

5.3. Quality Specifications

Typically, a dry-bright emulsion is tested for pH, percent solids, emulsion stability, and pigment reincorporation. Liquid shoe-polish efficacy is tested with respect to spectral reflectance (gloss meter), leveling, and pigment dispersion. The two latter analyses are conducted simply by pouring the product onto glass or an appropriate substrate and examining the results visually for "fish eyes" indicative of poor leveling or unincorporated pigment particles.

6. Other Shoe Dressings

Weatherproofing Liquids and Aerosols. Fluoropolymers such as FC-905 (Minnesota Mining and Manufacturing) are utilized to provide fine dress shoes with water and oil repellency. Titanate- curing polysiloxanes such as

Dow-Corning 477 are utilized for heavy-duty water repellency on work boots. These compounds provide an impervious coating upon drying; moisture from the air subsequently serves to cross-link the silicone polymer. Liquid products of this type are available, but aerosols are most popular because of their ease of application.

Leather Dyes. Solvent-based leather dyes are manufactured for professional and military applications. These products consist of black and brown solvent dyes in penetrating solvents such as toluene or xylene.

Silicone-Impregnated Sponges. Silicone polymers, both as emulsions or directly in the form of dimethyl silicone fluid of the appropriate viscosity, have been incorporated into sponges for the purpose of creating a quick temporary shine without any accompanying scuff restoration.

7. Environmental Protection

The heavy utilization of solvents in pastes, shoe creams, and weatherproofers is an industrial concern that offers the technical challenge of reducing the solvent levels without compromising the quality or efficacy of the products. Most major manufacturers are phasing out the use of ozone-depleting chemicals such as 1,1,1-trichloroethane and methylene chloride. There remains a heavy dependence on solvents for efficacious products, but on balance the extent of volatile organic compounds released into the atmosphere from this source is negligible in comparison with automobile emissions and other products and industries.

From a regulatory perspective, the toxicity profile of shoe-care products reflects the content of aromatic solvents. However, the infrequent use of such products, coupled with small package sizes (e.g., 30 – 60 g net content), mitigates any health risk. Dyes and pigments with severe carcinogenic profiles have been eliminated from most products.

Shortenings → Margarine and Shortenings
Silanes → Silicon Compounds, Inorganic

8. Economic Aspects

Major worldwide manufacturers of shoe dressings include Kiwi Brands, Tana, S. C. Johnson, and Reckitt & Colman. Worldwide production in each major product category is estimated as follows:

Paste polish	1.75×10^8 units
Shoe creams	1.90×10^8 units
Liquid polishes	2.25×10^8 units

Silica (SiO_2) is a commonly occurring compound in nature. Various crystalline and noncrystalline silica minerals of inorganic and biogenic origin are known. Depending on temperature, pressure, composition of the precursor phases, etc., several different crystalline modifications are formed. Quartz is the most abundant and well-known polymorph. Silica occurs as meter-sized quartz crystals or as amorphous masses made up of submicroscopic crystallites having different microstructures or growth fabrics. In addition, synthetic polymorphs have been produced for which no natural counterparts exist. In industry, quartz sand and silica rocks are widely used as raw materials for production of glass, ceramics, and silicon. Single crystals of quartz are grown artificially for application as resonator crystals in clocks, communication technology, and computer electronics. Both natural and synthetic silica powders are used as fillers to improve the mechanical properties of plastics.

1. Silica Modifications and Products

1.1. Occurrence and Geochemistry

Silica [*7631-86-9*], silicon dioxide, SiO_2, is the major constituent of rock-forming minerals in magmatic and metamorphic rocks. It is also an important component of sediments and soils [1 – 3]. Bound as silicates it accounts for ca. 75 wt % of the Earth's crust [4]. Free silica predominantly occurs as quartz, which makes up 12–14 wt % of the lithosphere.

Quartz is the thermodynamically stable modification at ambient conditions (Fig. 1) occurring as one of the main products of slowly cooled silica-rich magmas such as granites, granodiorites, and related rocks. It is also a primary mineral of pegmatites and hydrothermal veins formed during late stages of magmatic processes. In metamorphic rocks like schists, migmatites, and quartzites which suffered high temperature and pressure due to deep burial in the Earth's crust, quartz is also a major constituent. Owing to its hardness and low solubility, quartz is able to resist erosion and occurs abundantly in sedimentary rocks such as sand

and sandstones. Quartz is also the final product of the diagenesis process of noncrystalline biogenic silica deposited in sea floor sediments. In the form of chalcedony, microcrystalline quartz occurs as secondary filling of veins and cavities in rocks and in petrified wood and other organic matter. Flint nodules, frequently occurring in limestone formations, also consist of chalcedony.

Figure 1. Calculated phase diagram of the SiO_2 system [6]
H-Q: high quartz, L-Q: low quartz, C: high cristobalite, T: high tridymite (for the stability field of tridymite, see text).

Quartz owes its abundance to the action of water in rock-forming processes. In rocks that were formed at high temperatures under dry conditions – volcanic eruptiva, silicate meteorites, moon rocks and silica slags, for example – quartz is rare. Here the high-temperature silica modifications cristobalite and tridymite crystallize (Fig. 1). Under the influence of high pressure induced by burial in great depth or by meteoritic impact, the high-pressure modifications coesite and stishovite are stable.

Under more ambient conditions waterborne unstable silica varieties such as micro- and noncrystalline opals and chalcedony are formed. Deep-sea sediments consisting of large masses of biogenic silica, for example, are altered in a diagenetic process with increasing burial depth from noncrystalline opals via microcrystalline opals to chalcedony and chert. Micro- and noncrystalline silica minerals are described in more detail in [5].

Keatite, silica W, and porosils (except for melanophlogite) are artificial crystalline silica products that do not occur in nature. They do not have a stability field of their own and can be synthesized under hydrothermal conditions only in the presence of sodium (keatite) or with the aid of organic template molecules (porosils). The latter are described in more detail in Chapter 8.

Figure 2. Two-dimensional scheme of incorporation of impurities in silica
Top: chemical point defects introduced by occupation of silicon lattice sites and of interstitial sites by foreign atoms.
Bottom: water incorporated in the silica framework by forming hydrolytic nonbridging oxygen (German: *Trennstellen*) and by occupation of silicon vacancies or interstitial sites, and water located at the surface as silanol groups and adsorbed water molecules.

Silica crystals are almost pure SiO_2 which do not contain large quantities of impurities. Water, however, can be incorporated in concentrations from hundreds to several thousands of parts per million in quartz (Fig. 2). The transition from structural incorporation to microstructural inclusion is fluent [7]. At elevated temperatures and pressures water migrates rapidly through the structural framework by splitting Si−O−Si bonds and forming silanol groups. This mechanism of hydrolytic weakening activates plastic deformation, solid-state flow [8], reconstructive transformations, and recrystallization. Traces of alkali metal ions act as efficient transformation activators (Fig. 2) [9]. Alkali metal ions as well as Al and Fe are the most common nonvolatile impurities in silica. Quartz usually contains about 100 ppm of trace elements or less [5, 10, 11]. The concentration of impurities can be higher in tridymite and cristobalite than in quartz, ranging up to 5000 ppm Al, 3500 ppm Na and 1500 ppm K [12, 13]. The trace elements can be incorporated in at least two different ways (Fig. 2) [14]. The first is the substitution of Si^{4+} by Al^{3+}, or Fe^{3+} on lattice sites and simultaneous addition of Li^+, Na^+, K^+, Mg^{2+}, or Ca^{2+} on interstitial sites. The second is the incorporation of additional alkali metal ions to form alkaline nonbridging oxygen sites (German: *Trennstellen*).

1.2. Si−O Bond and Crystal Structures

Despite its chemical simplicity, SiO_2 displays a remarkable diversity of crystal structures. Apart from the ultrahigh-pressure modification stishovite with octahedrally coordinated silicon (Fig. 3) and artificial silica W with chains of edge-sharing tetrahedra, all crystal structures of silica are made up of a three-dimensional framework of corner-sharing tetrahedra (Fig. 3). The noncrystalline silica phases consist of a continuous random network of corner-sharing tetrahedra. All four sp^3 orbitals of silicon overlap with 2p orbitals of the four coordinating oxygen atoms to form strong σ bonds [15]. Additional minor contributions from π bonding may arise from overlap of Si 3d orbitals with other O 2p orbitals, which partly explains the observed shortening of Si−O bond lengths with increasing Si-O-Si bond angles [16]. The mixed bond character of about 50 % ionic and 50 % covalent results in bent intertetrahedral Si-O-Si angles in the range of 120 to 180° with a mean of about 147° [17 – 19]. Band theory treatment is given in [20]. The effective ionic radius of Si^{4+} is 0.026 nm for tetrahedral coordination by oxygen (O^{2-}: r = 0.135 nm), and 0.040 nm for octahedral coordination [21]. The mean Si−O bond length is 0.162 nm in the tetrahedra [22] and the mean O−O distance is 0.264 nm (Fig. 3). The short Si−O bond length is responsible for the high bond strength.

The strong bonds and the three-dimensional connectivity of the tetrahedra are the reasons for the high hardness (quartz: Mohs hardness 7), the lack of good cleavage, high elasticity, high melting point (cristobalite ca. 2000 K), high activation temperature of the quartz–cristobalite transformation (1300 K) and high transformation temperature of silica glass (1300 K). Contrasting with these properties, the resistivity of silica to electron irradiation damage is relatively low [23].

Silica is an insulator, a property that is utilized in the fabrication of silicon-based microelectronic devices by precipitation of ultrathin insulating films of noncrystalline silica on the semiconductor substrate crystals.

The tetrahedra can be considered as rigid units which remain almost unchanged upon thermal expansion or compression by high pressure. They are rotated or tilted instead. The variability of the intertetrahedral Si-O-Si angles and the unrestricted torsion angle of connected tetrahedra (Fig. 3) also account for the topological diversity of the crystal structures of silica and the tendency for glass formation. At elevated temperatures quartz, cristobalite, tridymite, and melanophlogite displacively transform into dynamically disordered high-temperature phases. Softening of rigid unit modes plays an important role in these thermally induced ferroic transitions [24]. In the variable framework structures, planar defects such as stacking faults in cristobalite and tridymite, and twin planes in quartz and moganite frequently occur. Growth twinning and transformation twinning are also common. Normally, neighboring tetrahedra adopt the electrostatically favorable trans configuration (Fig. 3). Rare exceptions with cis and trans configurations are tridymite [9], melanophlogite, and coesite [26].

Figure 3. Top: $SiO_{4/2}$ tetrahedron and $SiO_{6/3}$ octahedron.
Middle: tetrahedra configurations in the silica framework structures.
Bottom: stacking principles of idealized six-membered rings of tetrahedra: two-layer sequence in tridymite (left), three-layer sequence in cristobalite (right).

1.3. Crystalline Silica Phases

The crystalline silica minerals are listed in Tables 1, 2, and 3 together with their crystallographic data. Table 1 also lists the nonmineral crystalline phases keatite and silica W. The porosils are treated in Chapter 8.

1.3.1. Crystalline Silica Minerals

The *p–T* diagram of silica, with stishovite, coesite, quartz, and cristobalite, is shown in Figure 8 [6]. Tridymite forms only in the presence of impurities which act as mineralizers. The phase transformations between the stable phases are reconstructive, requiring breaking and formation of new Si−O bonds (except for the high quartz–low quartz transition). Apart from high quartz, all high-temperature and high-pressure phases can persist metastably under ambient conditions. Quartz and most of the phases that are metastable under ambient conditions undergo displacive transitions at elevated temperatures without breaking of bonds. Melanophlogite, moganite, and the microcrystalline mineral species have no thermodynamic stability field.

Quartz is the thermodynamically stable form under ambient conditions. The tetrahedra are arranged in the open structure of low or α-quartz as helices along the trigonal *c*-axis. Two types can be distinguished: a small helix formed by three tetrahedra and a larger double helix consisting of six tetrahedra. All threefold screw axes are either left- or right-handed, and this results in the optical activity of quartz with a rotatory power of 27.71°/nm for Na light [10]. The crystals are enantiomorphous with the symmetry of the acentric space groups $P3_121$ or $P3_221$. The right- and left-handed crystals are mirror images of each other (Fig. 4). The twofold symmetry axes perpendicular to the screw axis are polar, and mechanical stress along the axis produces a direct piezoelectric effect. The reverse effect is

Table 1. Crystalline silica phases: space groups and unit cell parameters

utilized in oscillatory devices. Standard values of important properties are compiled in [27], and the relationships between crystal structure and properties are given in [28]. The low specific free surface energy of the rhombohedral faces $\{10\bar{1}1\}$ results in a poor but distinct cleavage.

The thermal expansion of α-quartz is high ($\alpha_{11} = 13.3 \times 10^{-6}$ K^{-1}, $\alpha_{33} = 7.1 \times 10^{-6}$ K^{-1}) and drops to even slightly negative values at the displacive phase transition to high or β-quartz at 573 °C (Fig. 5). With increasing temperature the tetrahedra are rotated clockwise or anticlockwise around the dyad axes towards their higher symmetry positions in β-quartz. Additional dyad axes coinciding with the threefold screw axes in the double helices are generated at the transition, turning them into sixfold screw axes. The handedness of the helices is preserved, and the space groups for left- and right-handed β-quartz are $P6_222$ and $P6_422$ with additional twofold rotation axes perpendicular to the hexagonal c-axis (Fig. 4). The crystal structure of β-quartz is disordered by intense thermal vibrations of the tetrahedra, and the structure shown in Figure 4 is only an average. An intermediate phase occurs in a narrow temperature range of 1.7 K between α- and β-quartz. It is incommensurately modulated and consists of a regular array of microdomains with the orientation of twins according to the

Dauphiné law. The size of the domains rapidly decreases with increasing temperature [29]. Heating untwinned single crystals of quartz to temperatures above the transition point usually results in the formation of Dauphiné twins [30].

Dauphiné twins are intergrowths of two right- or two left-handed quartz individuals which are rotated by 180° with respect to each other around their common *c*-axis. This additional dyad axis is identical with the twofold axis which is lost during the high–low transition. Dauphiné twinning is also referred to as electrical twinning. Twinning according to the Brazil law also occurs abundantly in natural quartz, i.e., in amethyst and chalcedony. In this case right- and left-handed individuals are intergrown via the $\{10\bar{1}1\}$ plane. The new symmetry element introduced by the twinning is a mirror plane parallel to $\{11\bar{2}0\}$. Brazil twinning is also called optical twinning. Both kinds of twinning neutralize or reduce the piezoelectric effect of quartz, and crystals suitable for oscillatory and optical purposes must be free from twinning. Twins according to the Japanese law are less abundant. The twin plane is $\{11\bar{2}2\}$ and the *c*-axes of two twinned crystals form an angle of 84°33′.

Figure 4. Tetrahedral model of the crystal structures of left- and right-handed quartz. Top: low-temperature quartz; bottom: high-temperature quartz. Perspective view on (001) slices along the *c*-axis; [100] direction vertical.

Figure 5. Thermal expansion of the unit cells of cristobalite (top) and quartz (bottom).

Other compounds crystallizing with the quartz structure type are phosphates MPO_4 and arsenates $MAsO_4$ (M = Al, Ga, Fe), BeF_2, the high-temperature form of GeO_2, and the high-pressure modifications of BPO_4, $BAsO_4$, and phosphorus oxynitride (PON) [31 – 33]. β-Eucryptite $LiAlSiO_4$ and γ-spodumene $LiAlSi_2O_6$-III are stuffed derivatives of β-quartz in which the silicon atoms are partly replaced by Al and Li incorporated on interstitial tetrahedral sites (I_4 position) within the large helices [34].

Figure 6. Tetrahedral model of the crystal structure of cristobalite.
Top: (111) slice of the cubic high-temperature form ([$\bar{1}$10] direction vertical).
Bottom: (101) slice of the tetragonal low-temperature modification ([010] direction vertical).

Cristobalite is the low-pressure, high-temperature modification of silica (Fig. 1). It persists as metastable phase at low temperatures. A displacive phase transition from the tetragonal low-temperature α-form to the cubic high-temperature β-form takes place near 540 K. The transition is of first order with an hysteresis of more than 20 K and a volume discontinuity of ca. 5 %. The crystal structure of β-cristobalite is a derivative of the diamond structure type in which carbon is replaced by silicon and oxygen is located midway between neighboring Si atoms. The framework can be described as a stacking of parallel layers of six-membered rings of tetrahedra. Alternate tetrahedra point upwards and downwards (Fig. 6). The stacking is a three-layer sequence in cristobalite.In tridymite, similar layers are stacked in a two-layer sequence with antiparallel mutual orientation. Stacking faults occur frequently in cristobalite and tridymite (cf. microcrystalline opals). The space group of the average structure of β-cristobalite is $Fd\bar{3}m$ [35]. The rigid tetrahedra perform rotational vibrations by precessing around the straight Si-O-Si lines [36 – 39]. At the transition temperature, these motions become unstable, and the structure collapses to form oval rings instead of the hexagonal six-membered rings of tetrahedra in the average high-temperature structure. In α-cristobalite the tetrahedra are arranged in helices containing either left- or right-handed fourfold screw axes parallel to the tetragonal c-axis [36]. Two enantiomorphous forms exist with the space groups

$P4_12_12$ or $P4_32_12$. Loss of the threefold rotation axis, the inversion center, and the centering of the unit cell during the phase transition result in the formation of 12 twins and antiphase domains [40]. The volume discontinuity at the transition leads to characteristic fish-scale microcracking. These scales are rectangular if the cristobalite is structurally ordered and are rounded in the presence of stacking disorder [41]. The displacive cubic-to-tetragonal transition cannot be suppressed by quenching, but stacking faults lower the transformation temperature [138]. The structure of β-cristobalite can be stabilized by way of chemical stuffing. In $Ca_{0.02}Al_{0.09}Si_{0.91}O_2$ some of the silicon atoms are replaced by aluminum, and calcium ions are incorporated on interstitial sites in the large cages between the layers of tetrahedra [34].

Other compounds with the α-cristobalite-type of structure are the high-temperature forms of $AlPO_4$, $GaPO_4$, $MnPO_4$, and $AlAsO_4$ [31, 32]. $BAsO_4$, BPO_4, $BeSO_4$ and phosphorus oxynitride (PON) crystallize with the β-cristobalite structure. Stuffed derivatives are carnegieite $NaAlSiO_4$ [42] and a variety of compounds with the formula Na_2MSiO_4 (M = Ca, Be, Zn, Mg) [34].

Tridymite forms between 1200 and 1800 K at ambient pressure, but traces of foreign ions, preferably alkali metals, or hydrothermal conditions [43] are necessary. The growth of tabular crystals always starts with cristobalite nuclei [44].

The crystal structure is a derivative of the hexagonal wurtzite type with Si occupying the Zn and S positions and oxygen placed between the silicon atoms. Layers with six-membered rings of tetrahedra are stacked in antiparallel orientation to give a two-layer sequence. Viewed along the hexagonal *c*-axis the layers are in the totally eclipsed position in high-temperature tridymite, leaving open channels in the structure (Figs. 3 and 7).

With respect to bonding requirements, tridymite is much less balanced than cristobalite. As a consequence tridymite undergoes a cascade of displacive phase transitions [9, 45] (Fig. 8). Similar to β-cristobalite and β-quartz, the hexagonal high-temperature phase of tridymite is dynamically disordered [46]. Upon cooling, different rigid unit modes of the tetrahedra successively freeze in by forming phases with col-

[a] phases with incommensurate displacive modulations; [b] phase formed by thermal or mechanical stress (quenching or grinding); [c] transition temperatures depend on the degree of stacking disorder.
Nomenclature of the tridymite phases: L = low-temperature phase, H = high-temperature phase, T_O = ordered tridymite, T_D = stacking-disordered tridymite; in parentheses: M = monoclinic, O = orthorhombic, H = hexagonal, PO = pseudo-orthorhombic, C = C-centered, P = primitive Bravais type, S = superstructure, X = unknown.

lapsed rings of tetrahedra [47]. In a first step alternate layers of tetrahedra are laterally shifted with respect to each other near 400 °C, reducing the symmetry to orthorhombic [48]. In a second step an incommensurately modulated phase with temperature-dependent lattice parameter $\sqrt{3}a_{\mathrm{hex}}$ is formed at 220 °C [49, 50] which discontinuously locks in at ca. 150 °C resulting in a superstructure with a $3\sqrt{3}a_{\mathrm{hex}}$ lattice parameter [51, 52]. Finally, a monoclinic phase with a complex superstructure is formed at 116 °C in a first-order transformation [53, 54]. This modification is usually obtained by flux syntheses and has been found in moon rocks and meteorites. The transformation path, however, can be modified by thermal or mechanical stress or by lattice imperfections like stacking faults. Most tridymites occurring in terrestrial rocks contain stacking faults and have a triclinic (pseudo-orthorhombic) $2\times2\sqrt{3}\times10$ superlattice [55]. The number of high-temperature phases of pseudo-orthorhombic tridymite and the respective transition temperatures depend on the degree of stacking disorder [45]. A third room-temperature modification can be produced by grinding monoclinic tridymite or by quenching from high temperatures [56]. The phase is monoclinic and displays an incommensurate structural modulation [57 – 59]. Further modulated high-temperature phases can be obtained by reheating incommensurate low tridymite [60].

All three low tridymite modifications and cristobalite can be intergrown in the same crystal [60, 61]. Impurities can be incorporated by coupled substitution on lattice sites and on interstices in the open structural channels parallel to the *c*-axis [13]. In refractory-grade crystals, trace element concentration is 1 wt % [13].

A compound with isotypic phases is $AlPO_4$ [31]. Nepheline ($Na_3KAl_4Si_4O_{16}$) and kalsilite and kaliophilite (both $KAlSiO_4$) are stuffed derivatives of tridymite. Another stuffed derivative is $CaAl_2O_4$ [34].

Coesite is the high-pressure modification of silica with the densest framework of $SiO_{4/2}$ tetrahedra. It is composed of four membered rings of tetrahedra which are linked in the form of chains of rings. The chains are interconnected by symmetrically different four-membered rings of tetrahedra (Fig. 9). In this group the tetrahedra are in *cis* configuration with an exceptionally large Si-O-Si angle, restricted by symmetry to 180° [25, 26].

Figure 9. Polyhedral model of the high-pressure modifications coesite and stishovite.
Top: perspective view along the *c*-axis of stishovite ([110] direction vertical).
Bottom: (010) slice of coesite with vertical [101] direction.

Coesite metastably persists up to about 1300 K at ambient pressure. It is much less soluble in hydrofluoric acid than quartz but has a similar solubility to quartz in water under ambient conditions. Coesite and stishovite are rare and were synthesized prior to their detection in nature.

Stishovite crystallizes in the rutile structure type with silicon in sixfold coordination (Fig. 9). The SiO_6 octahedra form chains by sharing two opposite edges. Different chains are connected by linking of octahedra corners [64, 65]. The arrangement results in a very close packing of oxygen, even though the Si−O bonds are longer than in SiO_4 tetrahedra. Stishovite is about 43 % denser than coesite [66]. It is the stable form of silica under the conditions of the Earth's mantle. In the lower mantle stishovite probably transforms from the tetragonal rutile structure to a distorted structure with orthorhombic symmetry (stishovite II). A ferroelastic transformation to the denser $CaCl_2$ structure type is expected at higher pressures which involves tilting of the octahedra [66].

Figure 10. Tetrahedral models of the crystal structures of moganite and melanophlogite. (001) slices with vertical [010] direction.

Table 3. Microcrystalline silica minerals

Mineral or phase	Species *		Microstructure	Refractive index	Water content, wt %
Quartz	microquartz		granular grains $< 20\,\mu m$	1.54–1.55	< 0.3

		O-C_M	massy, tangled platy		1.0–8.0

* Ch: chalcedony, w: wall lining, h: horizontally banded, LF: length fast (negative optical character of the fiber elongation), LS: length slow (positive optical character of the fiber elongation), C: disordered cristobalite, CT: disordered cristobalite/tridymite, M: massy tangled

Moganite is closely related to quartz but represents a new structure type with a lower symmetry. The structure can be described as a composition of alternate $\{10\bar{1}1\}$ layers of right- and left-handed quartz (Fig. 10), that is, a periodic twinning according to the Brazil law on the cell-dimension scale [67]. The only known occurrence of pure moganite is on Gran Canaria, Spain, where it forms microcrystalline fillings of fissures and cooling cracks in the ignimbrite streams [68, 69]. It has been reported that moganite also occurs as a minor constituent of microcrystalline quartz minerals [70].

The synthesis of a high-pressure, high-temperature modification of phosphorus oxynitride (PON) with moganite-type crystal structure has been reported [33].

Melanophlogite is a very rare mineral with the composition $46\,SiO_2 \cdot 6\,(CO_2,N_2) \cdot 2\,(CH_4,N_2)$. Agrigento and Livorno in Italy and Mt. Hamilton in California are the only known noteworthy occurrences [71, 72]. The guest molecules CH_4, CO_2, and N_2 are incorporated in two types of large cagelike voids of the silica framework (Fig. 10) [73]. A displacive phase transition from tetragonal to cubic symmetry takes place between 40 and 65 °C. Melanophlogite is the only mineral species among the large group of artificial microporous silica phases which are treated in Chapter 8.

Chalcedony and quartzine are microcrystalline quartz minerals (Table 3) [5] consisting of submicroscopic fibers. The fiber elongation occurs perpendicular to the trigonal *c*-axis in chalcedony and parallel to it in quartzine. The microcrystals are highly defective and contain a large number of twin planes (left- and right-handed quartz twinned according to the Brazil law) [74]. Chalcedony is the main constituent of banded agate geodes, flint nodules, and chert. Quartzine sporadically occurs as thin bands in agates. The purity is usually high with less than 1 wt % nonvolatile impurities and less than 2 wt % water. The latter is incorporated at defects of the crystal structure and in the microstructure between the fibers [75].

Microcrystalline opals consist of highly stacking disordered cristobalite and tridymite. A distinction is drawn between opal-CT and opal-C [76, 77]. In opal-CT the stacking is random tridymitic (two-layer sequence) and cristobalitic (three-layer sequence) [78], whereas cristobalite dominates in opal-C [77, 79]. The microstructure consists of fibers (lussatite) or of lepidospheric aggregates of thin crystal blades (Table 3). The water content can reach 10 wt % with a large portion of water molecules dissolved in the defective crystal lattice [80, 81].

1.3.2. Crystalline Nonmineral Silica Phases

Keatite, silica W, zeosils, and most of the clathrasils are synthetic crystalline forms of silica for which no counterpart has been found in nature. The porosils are described in Chapter 8.

Keatite has a tetragonal framework of corner-sharing tetrahedra which contains five-, six-, and seven-membered rings of tetrahedra

[82]. Structural channels run parallel to the *a*-axes, and helices with fourfold screw axes parallel to the *c*-axis (Fig. 11) [83]. Under mild hydrothermal conditions microcrystalline fibers of keatite are obtained by using silica glass as starting material and dilute NaOH solutions [84]. It is a metastable intermediate crystallization product. Keatite can also be prepared under dry conditions by heating lithic silica gels with chromium oxide as additive [85].

Figure 11. Tetrahedral model of the crystal structures of keatite and silica W.
Top: (100) slice of keatite with vertical [001] direction.
Bottom: (110) slice of silica W with vertical [001] direction.

Stuffed derivatives of keatite are β-spodumene $LiAlSi_2O_6$ and $HAlSi_2O_6$, which show ionic conductivity.

Silica W [86] forms above ca. 1500 K in the vapor transport reaction:

$$H_2\,(g) + SiO_2\,(s) \rightarrow SiO\,(g) + H_2O\,(g)$$

The crystal structure is isotypic with that of SiS_2. Infinite chains of edge-sharing tetrahedra run parallel to one another and are held together by weak interatomic forces (Fig. 11). At ambient temperature, this very unstable configuration collapses immediately on coming into contact with traces of water. Tempering under the formation conditions produces cristobalite [86].

SiO_2-X is an alkali metal silicate hydrate with the approximate formula $MSi_{11}O_{20.5} \cdot 3\,H_2O$ (M = K, Rb, Cs) [87].

1.4. Noncrystalline Silica Minerals

Noncrystalline (antiquated: amorphous) silica has a short-range order of corner-sharing SiO_4 tetrahedra like crystalline silica but no long-range order and consists of a continuous random network instead of an ordered framework structure. The intertetrahedral Si−O−Si angles cover the full range from 120° to 180° with a maximum near 144° in silica glass [88]. The density of the network and other properties are variable. In nature, noncrystalline silica minerals are formed by melting and subsequent quenching (lechâtelierites), by pressure densification (diaplectic glasses), by rapid quenching of silica from hydrothermal solutions or by precipitation from a solution, sol, or gel near ambient conditions (opals). The range of Si−O−Si angles is narrower in opals than in silica glass [89]. The mean Si−O−Si angle is reduced in densified glass [90]. The mineral species are listed in Table 4.

Due to the lack of structural order and stoichiometry, the boundary between silica glass and silicate glass is fuzzy. For natural silica glass it can be arbitrarily drawn at about 3 mol % of nonsilica components. Opals, however, can contain considerable amounts of water and different varieties (opal-A_G and -A_N) can be distinguished by their microstructure and water content.

Lechâtelierites originate from molten silica formed by lightning strikes (fulgurites) or by meteoritic impact (meteoritic glass) on quartz sand or silica rocks [5, 10]. The glass body is featureless like synthetic fused silica but may contain some pores, inhomogeneities, and relicts of

Table 4. Noncrystalline silica minerals

Mineral or phase *	Species *	Microstructure	Refractive index	Water content, wt %

* A: noncrystalline; G: gel structure; N: network structure;
** e.g., Libyan desert glass.

quartz grains. The water content is usually less than 0.1 wt %.

Opal-A_G consists of a close packing of noncrystalline silica spheres with diameters ranging from ca. 100 to 500 nm. Water fills the interstices of the packing and is incorporated within the spheres [80]. Homodisperse spheres form a regular cubic, hexagonal or mixed closest packing [91], which gives rise to Bragg diffraction of visible light and produces the characteristic play of color of precious opals [92]. Heterodisperse spheres form irregular packings that result in diffuse scattering rather than in diffraction of light (potch opal).

Geyserite is precipitated in hot springs as sinter from silica-rich aqueous solutions. *Biogenic opal-AG* stems from plants (grass can contain up to 5 wt % silica, rice husks even up 19 wt %) or from skeletal remains of silica plankton. Silica deposits on the sea floor locally formed massive sediment layers with a total thickness of several hundreds of meters (e.g., Monterey, California). The water content usually ranges from 5 to 8 wt % (mostly molecular water) [5, 80] but can reach up to 16 wt % in biogenic opals [93].

Opal-A_N or hyalite is a water-containing silica glass that was formed in volcanically active areas by quenching of a silica-rich fluid or steam. It can be found as botryoidal crusts and fillings of vesicles in lava rocks [94]. The microstructure is characterized by striations parallel to the surface. Opal-A_N contains up to ca. 3.5 wt % water, almost 40 % of which is bound as silanol groups within the glass network [80, 95].

1.5. Colored Silica Minerals

Pure silica (e.g., rock crystal) is colorless. Except for precious opal, the color of silica originates from selective absorption by incorporated impurities forming so-called color centers. In several cases X-ray or γ radiation is necessary for the activation of the color centers. Heat treatment has an influence on the color, too. Several colored varieties of silica are traded as gem stones. Review articles on the origin of the color are given in [10, 96, 99].

Amethyst has a violet color due to the incorporation of Fe^{3+} on lattice sites and at I_4 interstitial sites in the helices of the quartz structure. Irradiation removes an electron from iron on lattice sites, turning it into Fe^{4+}. The electron is trapped by interstitial iron, which is reduced to Fe^{2+}. The color is not stable above ca. 300 °C but can be restored by renewed irradiation [97, 98].

Citrine is yellow to yellow brown with a smoky cast. It contains iron only at I_4 interstitial sites. If amethyst is heated in air at 300–560°C, iron oxide particles of submicroscopic size are exsolved, producing a yellow to yellow-brown color with reddish tints.

Rose quartz occurs as massy aggregates of quartz rather than as single crystals. The pale pink to deep rose color originates from Fe – Ti intervalence charge transfer in fibrous nanoinclusions of dumontierite or a closely related phase [100].

Smoky quartz or *morion* contains substitutional Al^{3+} on Si^{4+} lattice sites [101]. The black or grayish brown color is caused by irradiation, which produces an electron hole at oxygen bonded to aluminum. The color center is destroyed by heating above 200 °C but can be renewed by irradiation.

Other colored single-crystal quartz varieties such as pink or blue quartz have been found in nature or produced artificially but have gained only minor commercial importance as gemstones [102]. The color centers are often nonuniformly distributed, but for example in amethyst they are concentrated at Brazil twin boundaries parallel to the $\{10\bar{1}1\}$ faces [103].

Microcrystalline quartz minerals can be colored by inclusion of foreign pigment particles in the microstructure rather than by color centers in the crystal lattice. *Chrysoprase* is green due to submicroscopic nickel compounds, and the red or brown color of *jasper* is caused by Fe_2O_3 or $Fe(OH)_3$. *Agate* mainly consists of layers of translucent gray or white chalcedony which can be naturally or artificially colored by infiltration of iron or other compounds between the fibers. *Fire opal* is probably also colored red by Fe^{3+} pigmentation.

The colors of *precious opals*, however, are caused by Bragg diffraction of light and not by absorption. Therefore, the color is of higher spectral purity than in other gems. The diffraction originates from the ordered arrangement of homometric silica spheres and water with a lower refractive index in the interstices of the sphere packing. The maximum wavelength of the color depends on the size of the spheres. Opals containing large spheres produce all colors up to red whereas opals with smaller spheres show only a blue or violet color. Different orientations of grains with coherent sphere packing yield different colors. The play of color observed on turning a stone is enhanced by abundant stacking faults in the packing sequence of the silica spheres, producing diffraction streaks rather than sharp diffraction spots [91, 92].

1.6. Silica Rocks

Many special, trade, and trivial names exist for silica rocks, often with various meanings and imprecise definitions. A classification based on constituent silica phases and microstructure is given in Table 5 [2, 104, 105]. Silica rocks contain more than 90 wt % SiO_2. An ordinary sandstone, for instance, contains only about 65 wt % silica mainly as quartz grains. The rest is matrix and cement (feldspar, $CaCO_3$, mica, clay minerals, etc.). Transitions occur between silica rocks with increasing burial depth in the earth crust which not only result in a reduction of porosity and water content. Quartz sand is solidified to quartz sandstone (arenite or ganister) by cementation of the grains and grades by recrystallization into quartzite under pressure at elevated temperatures. Similarly, noncrystalline biogenetic silica remains of diatoms, radiolaria, etc. are transformed under compression into porcellanite and finally to chert. When the origin is known these rocks are designated as diatomite, radiolarite, or spiculite. Lydite and novaculite are radiolarites of paleozoic age. Tripoli is a friable porous porcellanite but the term is often used in a broader sense for abrasives and polishing media (Section 2.1). Ganister is a quartz sandstone cemented by chalcedony or opal-CT. Sandstone with less than 10 % matrix and cement is called arenite and with more than 10 % matrix wacke (quartz arenite and quartz wacke, respectively, when the total SiO_2 content is higher than 90 wt %). Chert nodules concentrated in layers of cretaceous chalk or limestone are called flint, silex (French), or Feuerstein (German). Agate geodes are fillings of vesicles in volcanic rocks, consisting mainly of chalcedony bands, interstratified by granular microquartz, quartzine, opal-C, opal-CT and coarse quartz crystals [107]. Further silica rocks and stones such as pegmatite quartz, vein quartz, sand, and gravel that are used as raw materials are treated in Chapter 2. A survey of industrial silica rocks is given in [108 – 110].

1.7. Crystalline Silica Products

Here only silica products made by crystallization from mobile mother phases or by transformation in the solid state are discussed. In contrast to the many noncrystalline silica products, crystalline products are limited to hydrothermally manmade quartz crystals and thermochemically produced polycrystalline silica.

Table 5. Silica rocks (> 90 wt % SiO_2)

Classification	Name	Main constituent silica minerals, microstructure	Special, trade, and trivial names (selection)
Sedimentary, nondetrital	diatomite (Chap. 3	opal-A_G; porous coherent diatom accumulation	kieselguhr [3]
	porcellanite	opal-CT; microporous rather strong rock	tripoli [106], opoka
	chert	chalcedony, granular microquartz; nonporous tough rock with conchoidal fracture	hornstein, novaculite, lydite, radiolarite, chert
Sedimentary, detrital	quartz sandstone	quartz grains cemented by direct contact, authigenic outgrowth, chalcedony or opal-CT	quartz arenite, quartz wacke, ganister, zementquartzite
Metamorphic	quartzite	recrystallized quartz grains and cement	crystalline quartzite, felsquartzite
Volcanic	geyserite	opal-A_G, opal-CT; friable, porous	silica sinter

Man-made or cultured quartz is of major economic importance and its use is growing. In contrast, the production of silica refractories for use in high-temperature processes is stagnating.

1.7.1. Cultured Quartz Single Crystals

Manufacture. The growth of quartz single crystals is carried out hydrothermally in sealed steel autoclaves with constant temperature difference and density-driven convection [111] (Fig. 12). Hydrothermal syntheses are defined as reactions or crystal growth at high pressures and temperatures in aqueous solutions, whether in the sub- or supercritical state [112].

Figure 12. Autoclave for quartz single crystal bar growth

Natural quartz [113] is fractionated into chips (lascas) of controlled size distribution (2.5–4 cm) and surface area. They serve as nutrient and are filled into an iron wire basket which is placed in the lower part of the autoclave. The lower part is separated from the upper part by a baffle of defined opening. Seed slices or rods, cut with defined crystallographic orientation from natural or man-made untwinned quartz crystals with a low content of structural defects, are hung in a rack and placed in the upper part of the autoclave. Preferred seeds are Z plates, cut parallel to $\{0001\}$, and Y rods, cut parallel to $\{11\bar{2}0\}$ and $\{0001\}$ and perpendicular to one of the a-axes.

Figure 13. p–T diagram of H_2O, isochores for various percentages of autoclave filling [115, 116]
C: critical point at 22.04 MPa, 547.4 K

Aqueous growth solutions with different mineralizers (mainly 0.5–2.0 M NaOH or Na_2CO_3 and additives such as Li_2O) fill ca. 70–80% of the inner autoclave volume. Special

syntheses, e.g., the growth of amethyst, which needs structural incorporation of traces of iron, require K_2CO_3 or NH_4F solutions [97, 114]. After sealing, the autoclave is electrically heated to a working temperature of ca. 675 K at the outer wall of the nutrient part (T_2) and ca. 20–40 K less at the seed part (T_1) (Fig. 12). The actual temperature difference ΔT in the reactor is much smaller (5–10 K). With increasing temperature, the pressure increases according to the percentage filling (Fig. 13). Under working conditions, it is ca. 100–150 MPa. A rupture disk in the pressure tubing at the seal prevents hazardous pressure increase.

During heating and cooling of the autoclave, at pressures below ca. 80 MPa, the hydrothermal system passes through a region of retrograde SiO_2 solubility. Above 80 MPa the solubility increases with temperature and pressure (Fig. 14). The mineralizers increase the solubility strongly, for example, at 673 K and 100 MPa from ca. 0.15 wt % SiO_2 for pure water to about 2–3 wt %. The solubility is approximately proportional to the mineralizer concentration [117]. Concentrations of NaOH or Na_2CO_3 above 2 mol/L, however, can lead to deposition of sodium silicate glass at the bottom of the autoclave, which obstructs the growth process.

Figure 14. Solubility of SiO_2 in H_2O [117]

In the nutrient section SiO_2 goes into solution. The solution at the bottom part of the autoclave has a higher temperature than the solution in the seed section and rises in the gravitational field due to its lower density. Above the baffle, it becomes cooler and supersaturated with SiO_2, and growth starts at the seeds. The cooled solution has a higher density and sinks into the nutrient section where it is warmed and becomes subsaturated. It dissolves silica from the nutrient and ascends, and so on in a permanent circulation driven by density difference until the desired quantity of nutrient has been transported to the growing quartz crystals.

The effective nonequilibrium distribution coefficient is defined as

$$k_{\mathrm{eff}} \approx C_{\mathrm{sact}} / C_{\mathrm{lact}}$$

where $C_{\mathrm{s\ act}}$ is the actual trace element concentration in the solid, and $C_{\mathrm{l\ act}}$ the actual trace element concentration in the liquid. The trace impurities accumulate in the solution [118] and the grown quartz crystals are of higher purity than the nutrient quartz. Doping with traces of special components changes the physical properties. For example, doping with LiF improves the electrical quality.

Raising *p*, *T*, and ΔT increases the rate of SiO_2 transport and of quartz growth. However, the high-temperature strength of the autoclave alloy sets limits on *p* and *T*. A low-pressure and a high-pressure process are usually applied. A pressure of 70–100 MPa, a temperature of 620 K, a temperature difference of 10 K, and a 0.6 to 0.8 M sodium carbonate solution are typical of the former and yield a growth rate of about 0.4 mm/d. The high-pressure process (100–150 MPa, 650 K, ΔT = 25 K, 1.0 M sodium hydroxide solution) yields a growth rate of up to 1.0 mm/d, but at the expense of higher costs for equipment [100]. The transition of convection from laminar to turbulent or even cellular flow with increasing ΔT limits these factors as well. Increasing face instability [118] and defect concentrations with increasing rates of transport set further restrictions.

The corrosion of the autoclave steel alloy is inhibited by formation of a dense coating of microcrystalline acmite $NaFe^{III}[Si_2O_6]$ and traces of emeleusite $LiNa_2Fe^{III}[Si_6O_{15}]$ by reaction with the growth solution.

The duration of growth runs varies between one and four months. The grown quartz crystals are formed by grinding to ca. 15–20 cm long bars. The orientation of the bars is determined by X-ray diffraction before cutting them

Table 6. Dimensions and yield capacities of autoclaves for man-made quartz

	Inner diameter, cm	Inner length, m	Inner volume, L	Yield per run, kg
Japan	65	13	4500	2000
United States	40	4.5	560	250

into wafers. An autoclave with 250 mm inner diameter and an inner length-to-diameter ratio of 12 gives a yield of ca. 100 kg of quartz bars per month. The loss by removal of seeds from the bars is ca. 20 wt %. Part of the cutting waste is used in the jewelry industry. The growth parameters which determine yield and quality of man-made quartz, are complexly coupled [120]. Dimensions and yield capacities of autoclaves are given in Table 6.

The largest production capacities exist in Japan, the United States, Russia, and China; smaller capacities are found in Europe, South Korea and South Africa. The total production of cultured quartz was estimated at about 200 t/a in the USA at an average value of ca. $ 186 per kilogram in 2005.

Small amounts of colored quartz [96] for jewelry are grown in Russia. While blue (Co-containing) and light green and yellow (Fe) quartz are already colored in the growth process, the Al and Fe color centers for smoky quartz and for amethyst must be activated after growth by γ radiation. Seeds for the first-mentioned color variations are Z plates, whereas for smoky quartz and amethyst X plates cut parallel to $\{10\bar{1}1\}$ are used because of face-specific incorporation requirements of the coloring elements.

Filter and oscillator quartz must be free of twinning and need low defect concentrations [121]. Structurally incorporated impurities are determined by chemical trace element analysis. Impurities which produce paramagnetic defects (e.g., Fe) can be detected by electron spin resonance spectroscopy [122]. Traces of water are determined by IR spectroscopy [123, 124]. Inclusions of foreign elements, depending on type, size, and position in the microstructure of the crystal are recognizable by X-ray diffraction, under the polarizing light microscope (PLM), or with the scanning electron microscope (SEM) and can be chemically analyzed by energy dispersive X-ray spectroscopy (EDS) in the SEM or with the electron microprobe [125]. Dislocations produce diffraction contrast in X-ray topography [126, 127]. Brazil twinning can be detected with PLM, but Dauphiné twinning can only be made visible by etching. Both types of twinning can be differentiated by X-ray topography [128, 129].

The quality of resonators is described by the electromechanical Q value. This dimensionless quality factor is defined as:

$$Q = \frac{2\pi f L}{R}$$

where f is resonance frequency, L inductance, and R resistance.

The Q value increases with decreasing energy loss due to relaxation and internal friction. The slower the decay of the oscillation amplitude after cutting off the excitation, the higher is Q. The quality of the quartz crystals contributes to the resonator Q value. The latter is not measured directly but a material Q is determined instead. A correlation between the IR absorption of structural OH groups (hydrolytic nonbridging oxygen, Fig. 2) at 3580 and 3410 cm^{-1} and the material Q value is usually utilized for quality control [130]. An empirical infrared a value is defined:

$$a = 1/t \log\ (T_{3800}/T_{3500})$$

where a is the extinction coefficient at 3500 cm^{-1}, t the thickness of the sample in centimeters, and T_n the transmittance at wave number n.

The material Q can be evaluated from

$$10^6/Q = 0.144 + 7.74a + 0.44a^2$$

The three highest grades have a material Q of 1.8, 2.2, or 3.0×10^6

Radiation in space, from uranium or thorium impurities, or from other sources affects the oscillator frequencies by acting on alkali metal impurities. Therefore the quartz must be grown to extreme purity Alkali metal ions on interstitial sites can be removed (swept) electrolytically after growth. This is done at elevated temperature (below the transition temperature of 573 °C in order to avoid electrical twinning) by applying a field of 1 kV/cm [119].

For further specification, the quartz bars are examined for inclusions which might contain

acmite impurities that stem from reaction of the hydrothermal solution with the steel walls of the autoclaves. The density of dislocations is determined microscopically after etching with ammonium bifluoride by counting the etch pits or channels. The best grades have dislocation densities of 10, 30, or 100 per cm^2.

Most of the cultured quartz is optically right-handed, as right-handed seed crystals are normally used. Electronic applications are treated in [131, 132]. Natural single-crystal quartz is now used only for a few special applications.

Despite the increasing demand, growth capacities are not markedly increasing because of improved cutting technologies, photolithographic etching, and miniaturization.

Figure 15. Illustration of the piezoelectric effect in quartz. Left: Simplified structural model of quartz viewed along the trigonal *c*-axis; small circles represent silicon and large circles two oxygen atoms. The trigonal a_i-axes and the orthogonal *x*-and *y*-axes are shown. Middle: Deformation of the structure due to stress applied along the *x*-axis (one of the three polar twofold rotation axes) produces charges on surfaces perpendicular to the *x*-axis (longitudinal direct piezoelectric effect). Right side: Stress applied along the *y*-axis also produces charges on the faces perpendicular to the *x*-axis (transverse direct piezoelectric effect). Change from compression to tension reverses the signs of the electric charges.

The Piezoelectric Effect of Quartz. If stress is applied along one of the three polar twofold rotation axes of quartz an electric polarization is produced (direct piezoelectric effect). The direction of the polarization vector is reversed upon changing from compressive to tensile stress and vice versa. Stress perpendicular to a polar axis and perpendicular to the trigonal *c*-axis (along the *y*-axis) also yields an electric polarization along the polar axis.

$$P_i = d_{ijk}\sigma_{jk}$$

i, j, k = 1, 2, 3
P_i = electric polarization
d_{ijk} = piezoelectric moduli
σ_{jk} = stress tensor

The anisotropy of the piezoelectric effect is described by a third-rank tensor with 27 components. Due to the symmetry of the stress tensor and the point-group symmetry of quartz (32) the number of independent components is reduced to two for quartz

$$d_{111} = -2.31\times10^{-12}\ \mathrm{C/N}$$

$$d_{123} = -0.727\times10^{-12}\ \mathrm{C/N}$$

for right-handed quartz (the signs of d_{ijk} are reversed for left-handed quartz [133]).

If an electric field is applied in appropriate direction the shape of a quartz crystal changes (<0.1 %). This is called the converse piezoelectric effect. An alternating electric field causes the crystal to vibrate.

$$\varepsilon_{jk} = d_{ijk}E_i$$

i, j, k = 1, 2, 3
E_i = electric field
d_{ijk} = piezoelectric moduli
ε_{jk} = strain tensor

Uses. The piezoelectric effect was detected by Pierre and Jacques Curie in 1880/1881 using quartz crystals. In 1917, the first sonar was constructed by Langevin to detect submarines. Since the 1920s quartz oscillators have been used for frequency control in radio broadcasting and communication electronics. The first oscillator for frequency stabilization, cut from natural quartz, was described 1921 by Cady [131]. A quartz crystal is stimulated to vibrate mechanically at its resonance frequency. The piezoelectric response in turn is then utilized for stabilization of the frequency of the circuit. The

use of quartz resonators increased as a consequence of the mass production of color TVs since the 1960s, quartz clocks and watches since the 1970s, and the developments in digital microelectronics. Today, virtually no appliance or device is working in communication electronics or computer technology without a quartz oscillator.

The resonance frequency depends on the cut and the shape of the quartz crystal. Initially, only cuts perpendicular to the *x*-axis were used for sonar transducers. Today, quartz tuning forks for wristwatches are produced from *x*-cuts. For other purposes, different cuts are preferred. So-called AT cuts are most commonly used. An AT-slice cuts the *y*-axis and forms an angle of 35.3° with the trigonal *c*-axis. As the d_{111} piezoelectric constant has a negative and the d_{123} constant a positive dependence on temperature, an AT cut provides independence of the resonance frequency from temperature [133].

In the megahertz range bulk waves are utilized. For the gigahertz range surface acoustic-wave devices are now produced by photolithographic techniques similar to those used in the semiconductor industry [119].

Due to its good elastic properties and very high stability, quartz is still the most important piezoelectric material. However, in the fields of ultrasonics and piezoelectric sensors and actuators, quartz is widely replaced by materials like lead zirconate titanate (PZT) ceramic which show a much stronger piezoelectric effect [134].

Other uses of quartz single crystals utilize optical properties like optical activity, birefringence, and dispersion.

1.7.2. Polycrystalline Silica Products

Refractory Silica. Dense shaped silica products consist per definitionem of greater than 93 wt % SiO_2 [135]. Usually, the silica content varies between 95 and 97 wt %. Refractory silica is available in three grades: superduty, regular duty, and coke-oven quality [136, 137]. Silica bricks are used up to 1925 K. The major applications of dense silica bricks are coke ovens, superstructures of glass-melting tanks, and hot-blast furnaces (checker bricks). Unshaped silica mixes are used for monolithic structures and repairs.

Silica Bricks. Raw materials for industrial silica brick production are high-grade quartzites or silica cemented quartz sandstones with >97 wt % SiO_2. The raw material is crushed, washed, and sieved. The sieve fractions are mixed to the desired grain size distribution. Small amounts of quartz sand are also used, and 1–4 wt % $Ca(OH)_2$ is added as mineralizer (transformation activator) and bonding agent. Sulfite lye acts as plastifier of the batch and provides sufficient strength for manual or mechanical shaping and drying. The bricks are fired at about 1700–1760 K in tunnel or shuttle kilns for one to three weeks (depending on their shape). The quartz raw material transforms into stacking-disordered cristobalite and tridymite under these conditions. The volume of the bricks increases by 4–5 % due to the higher specific volume of the high-temperature silica modifications. The amounts of cristobalite and tridymite depend on the raw material blend as well as on production parameters, mainly temperature and time of firing [138 – 140]. Tridymite forms only in the presence of suitable impurities and mineralizers; the longer the duration of firing the more is formed (see Section 1.3.1) [141 – 144]. The rate of the quartz transformation varies for the different types of raw materials. It depends mainly on the crystallite size distribution and on the amount and distribution of impurities (Al_2O_3, TiO_2, alkali metal oxides, Fe_2O_3). Quartzite transforms more sluggishly than quartz sandstone with a high content of microcrystalline quartz in the cement.

The burnt silica bricks contain small amounts of residual quartz (<6 wt %) and wollastonite $CaSiO_3$. The latter is a crystallization product of an intergranular glass phase ($SiO_2/CaO/Al_2O_3$). An excess of residual quartz must be avoided because of an irreversible after-expansion (Fig. 15) in service above ca. 1500 K, which is due to the transformation of the residual quartz into cristobalite/tridymite.

The content of residual quartz is easily determined by X-ray powder diffraction [145]. The quantitative determination of cristobalite and tridymite, however, is difficult due to their structural defects [138, 139], and large errors can result if these are not taken into account [146].

Silica bricks expand on heating and reach a maximum between 1075 and 1275 K of ca.

Table 7. Material properties of dense silica bricks [149]

Application	Bulk density, g/cm^3	Apparent porosity, vol %	Cold crushing strength, MPa	Refractoriness under load (differential) T_{05}, °C	Thermal expansion 1000 °C, %	Thermal conductivity 1000 °C, W m^{-1} K^{-1}
Coke oven	1.78–1.90	18–23	30–60	1610–1650	1.3	1.8–2.2
Glass furnace	1.81–1.85	19.5–21.5	30–40	1630–1670	1.4–1.5	1.8–1.9

1.3–1.5 vol % and have a small negative expansion at higher temperatures (normally 0.1–0.2 vol %) which is attributed to a structural contraction of the tridymite and cristobalite components [147, 148]. Due to the comparatively low thermal expansion, refractory silica has a very good thermal shock resistance above 875 K. Below this temperature, however, extreme care must be taken on heating and cooling to avoid cracking. A further valuable feature is the extraordinarily good creep behavior of refractory silica under compression at high temperatures. This is attributed to the very small content of liquid phase which is due to the low content of impurities (in particular, < 1.5 wt % Al_2O_3 and < 0.4 wt % alkali). Silica bricks are used up to 1925 K. The corrosion resistance against acid slags is good. However, alkali-containing vapor may cause corrosion by melt formation below 1750 K.

Table 7 gives a survey of the properties of silica bricks. For the production of very dense silica bricks with high thermal conductivity, Si_3N_4 or SiC is mixed into the raw batch. During firing these compounds are oxidized, and the resulting crystalline silica fills the intergranular pores [150, 151].

During operation in a temperature gradient, silica bricks develop zones with different microstructures and silica phases without significant change of shape. Above ca. 1730 K cristobalite predominates, and between 1580 and 1680 K tridymite [147, 152, 153].

The major applications of dense silica bricks are coke ovens, superstructures of glass-melting tanks, and hot-blast furnaces (checker bricks). Unshaped silica mixes are used for monolithic structures and repairs.

Cristobalite sand, powder, and flour are produced from quartz sand by calcination in rotary furnaces at 1800 K or from flint in shaft furnaces with subsequent grinding in ball mills. Another route works with processed sand and addition of mineralizers at 1500 to 1700 K, leading to products with > 99 wt % SiO_2. The former products are used as refractory mortars and ramming mixes in ceramic kilns and for blending with quartz or other mineral sands for various uses (e.g., in foundries) preferably as a modifier of thermal expansion. Heat-insulating lightweight (up to 60 % porosity) silica refractories are produced by addition of material that burns off during firing (e.g., sawdust, cork). Diatomaceous earth (see Chap. 3) can also be used as raw material. Burned diatomite consists of about 80 wt % crystalline silica, mainly cristobalite with some quartz. It serves as heat-insulating material for use up to 1200 K.

High-purity cristobalite from processed sand serves as weathering- and exhaust-resistant white filler which has no yellow shade for thermoplastic road marking (flour as pigment, sand as antiskid), for production of plastics, adhesives, wall paint, and texture coatings. Surface treated (preferably with siloxanes) flour is incorporated into silicone rubber and cable coverings and into EVA or PE foils as IR absorber. It is used for glaze frits, engobes, and other ceramics inter alia as modifier of thermal expansion. In silicate chemistry it serves as raw material.

Rice husk ash is prepared by burning the husks at about 800–900 K for ca. 2 h. The husks contain ca. 9–19 wt % noncrystalline silica, the ashes ca. 85 wt %. They are used as additives to Portland cement for reduction of the alkali–silica reaction and the detrimental cracking that is caused by this reaction [154].

Refractory silica cloth is replacing asbestos. It consists of 8–10 mm thick glass fibers with a silica content of more than 96 %.

1.8. Noncrystalline Silica Products

Most of the noncrystalline silica products are treated in Chapters 3, 4, 5, 6, 7. Only silica glass and silica fume are briefly described here.

Table 8. Physical forms of quartz raw materials

Name	Formation and properties	Remarks, synonyms, and trivial names
Idiomorphic quartz	freely grown, euhedral faced, monocrystalline, possibly twinned, transparent colorless or smoky to dark brown or black	rock crystal, smoky quartz
Lump quartz	fragmented, anhedral, monocrystalline, may be twinned, transparent, colorless, smoky, milky, or white	chunk quartz, lascas, brazil pebbles, lump silica
Quartz pebbles	weathering product from quartz veins, worn by action of water, smoothly rounded, mono- or polycrystalline, transparent to white or yellowish white or gray	if transparent: rhinestone or rheinkiesel, grain size 2–60 mm
Granular quartz	xenomorphic product of natural (weathering) or industrial processing from granitic–pegmatitic rocks, monocrystalline, may be twinned, transparent to translucent, yellowish, gray, or smoky	grain size 0.5–1 mm [159]
Quartz sand	unconsolidated, wind- or water-eroded and transported weathering product of fragmented rocks, grumbled into mono- or polycrystalline grains, rounded or angular anhedral, the majority of grains are discernible with the naked eye, white to yellowish in bulk, in the individual grain transparent to translucent	silica sand, grain size 0.06–2.0 mm
Quartz powder	unconsolidated product of grinding or milling of coarser quartz, individual grains not discernible with the naked eye, white opaque in bulk	quartz flour, silica powder, silica flour, grain size 0.002–0.06 mm
Quartz rock	intergrowth of quartz grains or consolidated by cementation of grains	quartzite, quartz sandstones, see text and Table 5

Silica glass is pure vitreous silica with diverse industrial applications. It is produced either by melting natural quartz crystals above 2050 K (fused quartz) or by vapor-phase hydrolysis of $SiCl_4$ in a methane oxygen flame (fused silica). The use of vitreous silica produced by sol–gel processes is restricted to thin-film technologies. The main benefits of silica glass are broad transparency to ultraviolet to near infrared, high resistance to thermal shock due to the low thermal expansion of 5.5×10^{-7} K^{-1} and high chemical corrosion resistance [155]. These properties led to uses as optical material, optical waveguides and chemical apparatus. Silicate glass is treated in detail in → Glass.

Silica fume is a very fine powder consisting of noncrystalline silica spheres with an average diameter of ca. 0.1 µm. It forms at temperatures of about 2050 K as a byproduct of the reduction of quartz in electric arc furnaces for the production of silicon and ferrosilicon. The silica vapor is condensed and collected to prevent its emission. Silica fume is mainly used as an admixture in cement, concrete, and mortars to improve strength and durability. Due to the small particle size and the large surface area (up to 30 m^2/g), it acts both as a microfiller that reduces the porosity and as a pozzolan which reacts with the calcium hydroxide from the cement [156].

2. Quartz Raw Materials

2.1. Physical Forms and Occurrence

The range of quartz in nature is vast. Table 9 describes the physical forms and Table 9 lists the geological occurrences of raw materials [157 – 166].

Table 9. Geological occurrence of quartz raw materials

Name	Occurrence	Remarks
Idiomorphic quartz	grown in veins, vugs, vesicles, and shear fissures of igneous, metamorphic, or sedimentary rocks	chemical purity and transparency increases from base to top of crystal
Vein quartz	xenomorphic and dense quartz filling of veins, cracks, faults, dikes, bedding planes, fractures, or joints in zones of structural weakness of igneous, metamorphic, or sedimentary rocks	
Pegmatite quartz	polymineralic veins, most frequently of granitic composition (quartz, feldspar, mica), however, it may be of any other composition, or coarse crystalline areas in granites or other igneous plutonic rocks but also in metamorphic rocks with all transitions to the rock itself	
Quartz from disseminated hydrothermal deposits	polymineralic fillings of dispersed vein systems in large volumes of rocks, dissemination along cracks and fractures or in zones of high permeability for hydrothermal solutions	quartz frequently contains fluid and solid inclusions [174, 205] (Fig. 16)
Quartz gravel and sand	occurrences are widespread and diverse, mainly in cretaceous, tertiary, and alluvial beddings; detrital product obtained from rocks by various weathering, transport, selection, and bedding conditions [204 – 207]	

The main characteristics of quartz raw materials are grain size and shape, their distribution functions, surface area and roughness, sorption capacity [163], chemistry, physical properties, and cost. Increasing demand for extremely pure quartz for silica glass production and in the quartz oscillator industry, and the growing use of refined grades of sand makes consistency and long-term availability important [161].

Impurities and their accessibility to refining processes are of major importance. In most cases, trace element analysis gives bulk composition and no information about the location of impurities in the microstructure. This, however, is essential for choice of quartz processing methods. Figure 16 shows the principles of impurity distribution in a crystal.

Quartz gravel and sand are the most important raw materials on a volume basis; the construction industry consumes about 95 % of production (ca. 65 % structural and ca. 30 % civil engineering). In 1995 Germany produced 18×10^6 t of sand (56 % river sand, 44 % high-purity sand with > 98 wt % SiO_2). The overwhelming part of the sand supply for Europe comes from Belgium, Germany, and the Netherlands. In 1995 the EU produced ca 16×10^6 t of high-purity sand. The main consumers were the float- and container-glass industry with rising customer specifications [167]. Recycling of glass reduced the demand for sand in container glassworks.

Tripoli contains ca. 98–99 wt % SiO_2. It occurs in sedimentary strata as a leaching product of calcareous cherts or siliceous limestones. White tripoli is low in iron impurities (< 0.1 wt % Fe_2O_3); rose or cream tripoli contains up to 1 wt % Fe_2O_3. It consists of submicroscopic quartz crystallites. Particles with sizes 5 to 100 µm are crystallite aggregates. White Southern Illinois Tripoli has the composition SiO_2 99.5, Al_2O_3 0.009, Fe_2O_3 0.025, CaO 0.15, TiO_2 0.005 wt %.

Kieselerde is a natural mixture of quartz and kaolinite [168]. The mineralogical and chemical composition of Kieselerde from Neuburg (Donau) follows [168]: 62–84 wt % quartz, 10–30 wt % kaolinite (content increases with decreasing grain size), 6–8 wt % accessorial minerals; 78–87 wt % SiO_2, 8–14 wt % Al_2O_3, $<$ 1 wt % Fe_2O_3, 60 ppm P, and 35 ppm S (both relative to Si).

Chalcedonies (Section 1.3.1) are classified according to their deposition as wall-banded Ch-w or horizontally-banded Ch-h (Table 3). According to the optical character of their fiber elongation, two varieties can be distinguished: chalcedony with length-fast elongation: Ch-w_{LF} and Ch-h_{LF} and quartzine Ch_{LS} with length-slow elongation. Chalcedonies occur in various geological environments, filling veins, vugs, and vesicles in volcanic rocks, sediments, ore deposits, or covering and impregnating plants in regions with volcanic activity [169, 170].

Ch-w is bluish gray in reflected and brownish in transmitted light due to Rayleigh scattering. It has a brown color if it was impregnated with ferrous humic acid waters (then called sarder). It possesses an open submicroporosity which makes it artificially impregnable with coloring solutions and allows penetration of liquid impurities. The microstructure is monomineralic, of high toughness, and high purity, which makes it a good material for milling devices, mortars, and bearing stones.

Chalcedony is slightly weaker than quartzine. If quartzine is interstratified into chalcedony layers, it forms a raised abrasion relief [171]. Since the resistance to HF etching is reverse, etch leveling is possible. Ch-h has almost no open porosity.

2.2. Processing

Impurities may be fixed on the surfaces of the individual quartz crystals or grains. Then they are rather easily accessible for removal. If they are included as minerals or fluids in the microstructure (Fig. 16) [163, 172, 173], the crystals must be crushed for removal. If the impurities are incorporated into the crystal structure, dissolution of the crystal is required for removal. Detrimental accessory minerals in quartz sands are mainly rutile, zircon, tourmalines, magnetite, hematite, ilmenite, chromite, Mn oxides, feldspars, and clay minerals.

Purity grades of processed natural quartz raw materials are [159]:

Figure 16. Principles of impurity distribution in a single crystal.
A) Structural incorporation
a) Random; b) Growth sector specific; c) Zonal
B) Microstructural inclusion
d) Skeletal growth and face specific adsorption, possibly with subsequent overgrowth; e) Dendritic growth or precipitation; f) Accumulated and accidentally ingrown, e.g., in fissures or dendritic cavities.
C) Types of fluid inclusions in quartz [174 – 176].
v = vapor, l = liquid; squares, rectangles, and triangles represent crystallites.

Grade	**Impurity content (ppm Si)**
Low	> 500
Medium high	300–500
High	2–50
Ultrahigh	1–8

Processing of coarse monocrystalline quartz to lumps or lascas [159]:

- Size reduction (weight specification for lascas ca. 15–50 g)
- Under water: sorting out of pieces with visible inclusions; under UV light: fluorescent pieces
- Under visible light: sorting of different grades of transparency.

Product: various grades of lascas.

A special process is γ-irradiation-aided selection of lascas [159]:

- Irradiation with doses ≤ 1 Mrad
- Color sorting [177]; the depth of color is mainly a function of the Li/Al trace element concentration ratio (Fig. 17)

Figure 17. Irradiation color (γ radiation, 1 Mrad) and Li/Al concentration relationship for initially colorless first-grade lascas (Minas Gerais, Brazil) [159].

Processing of quartz rocks, vein quartz, and quartz from disseminated hydrothermal deposits:

– Breaking and sieving.

Product: quartz of low chemical purity for production of high purity silicon compounds.

Processing of granular quartz from deeply weathered feldspathic rocks [159]:

– Crushing and grinding
– Multistage flotation
– High-field magnetic separation
– Chemical treatment with dilute sulfuric or oxalic acid or chlorination at ca. 600 K
– Sieving

Product: medium- to high-purity granular quartz (type QUINTUS, Unimin Corp. New Canaan, Connecticut, USA).

– Acid (HF) leaching
– Elutriation with deionized water to pH ≥ 6
– Vacuum drying
– High-field magnetic separation
– Chlorination at ca. 1400 K

Product: high-purity granular quartz (type IOTA, Unimin Corp., New Canaan, Connecticut, USA; Table 10) preferably for production of silica glass implements: halogen and high-intensity discharge lamp tubings and semiconductor applications such as Czochralski crucibles and diffusion tubes.

Processing of quartz gravel:

– Separation of sand
– Washing
– Sizing and drying

Product: filter pebbles, beach pebbles for milling stones, gravel for concrete.

Processing of quartz sand [178, 179] varies depending on the required grade. Process steps are:

– Washing in water to remove loose impurities
– Friction washing (attrition)
– Crushing of agglomerated grains in water
– Rubbing off strongly adhering impurities (iron oxides and oxide hydrates, clay minerals)
– Screening
– Multistage flotation to remove accessory minerals
– Chemical treatment with aqueous acids (sulfuric, oxalic, fluoric)
– Chlorination at ca. 600 K
– Physical treatment by magnetic and electrostatic separation of iron oxide and feldspar contaminants
– Surface treatment with amino-, epoxy-, methyl-, methacryl-, or vinylsilanes [180, 181].

Sand for use in cement-based products should be free of chlorides and clay minerals. Sand for special mortars must be freed from organic residues by calcination [182].

Quartz powders are produced by dry grinding in encapsulated mills with chert or corundum lining and balls. Refining of powder from high-purity vein quartz gives grades with 8–50 ppm Fe/Si.

Processing of quartz rocks includes breaking, milling, sieving, washing, and sizing [178, 179].

Biological removal of iron impurities with cultures of acid-producing bacteria or fungi (e.g., *Aspergillus niger*) on a nutrient of molasses is discussed in [183].

2.3. Uses

Important uses of quartz raw materials or semifinished materials are listed below [161]:

Use	Raw or semifinished material
Abrasives and grinding media	sand, powder, tripoli, novaculite
Ceramics	quartzite, quartz-cemented sandstone, sand, powder
Chemicals	sand, powder
Construction of buildings and roads	gravel, sand, powder, quartzite, sandstone
Fillers, extenders	powder, tripoli
Filters	gravel, sand
Foundry	sand
Gems	monocrystalline quartz, chalcedony, agate, chert
Glasses, enamels, glazes	sand, powder
Hydrothermal growth of quartz single crystals	lump quartz, granular quartz

Table 10. Trace element analyses (ppm/Si) of UNIMIN-JOTA-quartz grades [208]

Grade	Li		Na		K		Ca		B		Al		Fe	
	min.	max.	min.	max.	min.	max.	min.	max.	min.	max.	min.	max.	min.	max.
Standard ST	0.7	1.5	0.9	1.5	0.7	1.5	0.4	1.5	0.08	0.10	15.2	22.0	0.3	1.5
JOTA-4	0.2	1.0	1.0	1.3	0.4	1.0	0.6	1.0	0.04	0.05	7.9	10.0	0.6	1.0
JOTA-6	0.2	0.3	0.1	0.2	0.1	0.2	0.5	0.7	0.03	0.04	7.9	9.5	0.2	0.3

Metallurgy	quartzite, sandstone, sand, powder
Milling	silex, chalcedony, flint, quartzite
Optical and oscillator devices	monocrystalline man-made and natural quartz
Silicon metallurgical grade, silicon alloys	lump quartz, quartzite, quartz-cemented sandstone
Vitreous silica	lump quartz, granular quartz, sand
Well fracturing	sand

Abrasives and Grinding Quartz. Quartz sand and powder are used for grinding, scouring, and polishing. The conchoidal fracture, hardness, and brittleness provide and maintain particles with sharp cutting edges during use. The use of quartz in sandblasting is decreasing due to health hazards (Chap. 9). Quartz sand is also of declining importance for sandpaper. Quartz powder is utilized in abrasive soaps and in scouring powders. Sandstones are used for grinding. Tripoli is friable and its grains have no sharp edges. Tripoli grades with 98–99 wt % SiO_2 are used for polishing [184]. Novaculite (Table 5) from Arkansas and Missouri, USA, has a microstructure of minute angular quartz grains with open porosity. It is used as oil-soaking whet- and honing stone. Whetstone grades range in porosity from 0.1 to 15 % [184].

Ceramics and Refractories. Batches for stoneware, porcelain, fireclays, and aluminum silicate refractories contain quartz as a nonplastic filler and glass former. White-burning, low-iron quartz powders produced from sand, flint, or quartz rocks are used. Flint is calcined before grinding. In pottery and earthenware, quartz sand and powder act as nonplastic fillers [185]. For silica refractories, see Section 1.7.2.

Chemicals. A wide range of chemicals is produced from quartz. Here, only one important product that is representative of different reaction processes and reaction temperatures, is briefly described.

Sodium or potassium silicate (waterglass; → Silicates) are melted from quartz sand and the alkali metal carbonates. Usually, the sand is of container-glass grade with < 0.1 wt % each of Al_2O_3 and CaO and a very low iron content ($<$ 0.02 wt % Fe_2O_3). Very high purity products require sand with < 0.02 wt % Al_2O_3 and CaO each. Melting is performed in tank furnaces at ca. 1700 K (furnace route) [186].

Waterglass from the hydrothermal route is produced in autoclaves by reaction of quartz sand with aqueous NaOH solution at ca. 430–500 K.

Construction of Buildings and Roads. Quartz sand and gravel are an integral part of asphalt, mortars, and concrete. For good rheological behavior sand or gravel should consist of well-rounded grains or pebbles. Optimized grain size distribution minimizes water demand and shrinkage in the setting reaction and contributes to the development of high binder strength. Quartz sandstones with various cementing material and quartzites have long be used as building stones [187]. Bricks and tiles are fired from mixtures of quartz sand and clay.

Since 1894 when the first calcium silicate (CS) units were industrially produced [188], their use for masonry in central Europe has rapidly developed [189].

Quartz sand (fluviatile) from a broad coastal strip of the Netherlands and North Germany (about 18×10^6 t/a) is processed according to the following (simplified) process scheme:

- Mixing and pretreatment of sand, lime, and water
- Densification and shaping by pressing
- Hardening in the autoclave with steam or water at about 16 bar and 475 K for ca. 6–8 h

In the hardening reaction, the calcium silicate hydrate (CSH) phases, preferably tobermorite and xonotlite, form a cement between the quartz grains. This gives the units a high com-

pression strength. Essential process parameters for the quartz sand are: grain size distribution (sieve line) and the shape and surface of the grains. The accessory minerals [mostly (in wt %) ≤ 5 feldspars and micas, ≤ 3 clay minerals, ≤ 3 calcium carbonates, ≤ 1 iron manganese oxides and oxide hydrates] [190] take part in the hardening reaction. Fe and Mn enter the crystal structures of the CSH phases as doubly charged ions and produce almost no hue. Humic matter spoils the process. About 1.5 t of sand is needed for the production of 1 m^3 CS units. In central Europe CS masonry is appreciated mainly due to its high raw density and sound absorption, its heat capacity and resistance against fire, and the good compression strength which allows the construction of space-saving walls.

Oil Well Cementing. Heat in the depth of oil wells converts the calcium silicate hydrate (CSH) gel of tobermorite character in the settling portland cement with its good cementing properties into α-dicalcium silicate hydrate (α-C_2SH). This causes the development of a porous and weak microstructure with open pathways for corrosive fluids. Addition of quartz sand and powder prevents this deteriorating transformation. Portland cements for use at very high temperatures contain 35–50 wt % of SiO_2 additives [191].

Fillers and Extenders [192 – 194]**.** Quartz and cristobalite fillers are hard and strong with high resistance against chemicals and weathering. They give the final product a characteristic dependence on thermal expansion. In paints, quartz increases the acid resistance and improves flowability, durability, and wear resistance. Silane-treated fillers [195] are used for corrosion prevention in primers instead of heavy metal pigments [196]. In engineering plastics and resins, compressive and flexural strength and thermal shock resistance are improved. The insulator character of quartz and its resistivity to surface leakage currents make it a valuable filler for epoxy resin encapsulations, high-voltage insulation, bushings, switch cases, cast resin transformers, and for filling and fixing of coils. For example, reaction hardening resins may contain up to 80 wt % SiO_2. Silane-treated quartz powder in epoxy castings reduces shrinkage and electrical loss, increases E moduli, compression strength, and thermal conductivity [197, 198]. Quartz is used as a filler in rubbers instead of carbon black when colors other than black are required. In tire linings, it gives improved heat aging, adhesion, and tear strength.

Filters. Quartz pebbles, preferably monocrystalline, and sand are the main filter materials for drinking water purification and softening.

Foundry Technology [160, 178, 179, 199]. Quartz sand is used in molds and cores. Refractoriness (i.e., the temperature at which sintering begins; ca. 1500–1700 K, depending on the content of feldspar), thermal shock resistance, cohesiveness in the moist state, and high-temperature strength are the most important properties. For cast iron, the mold must contain > 85 wt % SiO_2 and for steel castings 95 wt %. Granulometric factors such as particle size distribution, grain shape, state of grain surfaces, and surface area are also important. Coarse sand with low surface area requires less binding agent (usually montmorillonitic clay). Monocrystalline well-rounded grains ensure good permeability to gases evolved during casting. Mold surfaces made of fine sand give smooth molding surfaces that do not require machine finishing. The sands may naturally contain enough clay minerals for good mold strength, or require additional binders, which increases costs.

Specifications for foundry sand grades of different refractoriness:

Beginning of sintering, K	> 1775	1575–1775	< 1575
Quartz, wt % (rest: feldspar and clay minerals)	>99	95–99	< 95

Glasses, Enamels, and Glazes [161, 167, 186, 200 – 204]. Different types of glasses and enamels require various grades of quartz raw materials. The silica content of glazes is mainly supplied by the silicate ingredients (feldspar, clay). If additional SiO_2 is required, quartz or flint powder is added.

Hydrothermal Growth of Quartz [159] (Section 1.7.1). Brazilian lascas were used worldwide as nutrient chips until the Brazilian quartz embargo in 1974. Since then, many other sources for high-purity low-cost lump quartz and granular nutrient were made accessible.

Metallurgical-Grade Silicon, Silicon Alloys and Silicon Carbide (→ Silicon; → Silicon Carbide). For chemical- or metallurgical-grade silicon, quartz lumps or pebbles (25–150 mm) are reduced with coke in electric-arc furnaces. The lumps and pebbles must not decrepitate during heating and therefore should preferably be monocrystalline and free of fluid inclusions. The grade of quartz raw material depends on the required grade of the products. Metallurgical-grade silicon with 99.0 wt % Si requires (in wt %): $\geq$ 99.0 SiO_2, $\leq$ 0.2 Al_2O_3, $\leq$ 0.1 Fe_2O_3, $\leq$ 0.1 MgO and CaO each, $\leq$ 0.02 TiO_2.

Low-grade silicon (98 wt % Si) for steel and aluminum production needs quartz with (in wt %): 98 SiO_2, $\leq$ 0.4 Al_2O_3, 0.2 Fe_2O_3, $\leq$ 0.2 MgO and CaO each, $\leq$ 0.1 P_2O_5, $\leq$ 0.002 TiO_2.

Production of 1 t metallurgical-grade silicon requires ca. 2.5 t of quartz. The worldwide silicon production is ca. 650 000 t/a.

Metallurgy. Quartz in the form of lumps or granules of vein quartz, quartzite, or sandstone is used as a flux in melting metal ores, for slagging iron oxides and basic oxides, and for balancing the silica/lime ratio of blast furnace burdens. In both cases, the SiO_2 content must be >90 wt % with lumps and granules in the size range of 0.8–2.5 cm.

For welding fluxes, quartz powder is used with a controlled grain size distribution of < 0.25 mm with an average of 0.06 mm for coated standard electrodes. The size of quartz particles in agglomerated fluxes must be < 0.06 mm.

Milling. Nodular chert (flint, silex) and very finely crystalline quartzite with > 96 wt % SiO_2 and homogeneous microstructure serve as linings for mills. Rounded flint nodules are preferably used as grinding pebbles.

Belgian silex consists of chalcedonic silica with evenly distributed calcite as secondary mineral phase and represents a material with high overall toughness. Yugoslavian silex has a coarser microstructure and sometimes contains coarse quartzite but is nevertheless of very good durability. Quartzite can only be used if it is free of accessory minerals. Translucent iron-free chalcedony from agates is used in ball mills and mortars for size reduction of high-purity quartz and silica glass.

Quartz for Optical and Oscillator Devices. Natural monocrystalline idiomorphic quartz is preferably used for optical devices as wafer plates, Brewster windows and prisms, birefringent filters, and tuning elements for laser optics. Only small amounts of man-made quartz are used in these applications. Oscillator quartz devices, however, are almost exclusively made from man-made quartz, for reasons of quality (low damping) and cost advantages.

Vitreous Silica. Transparent silica glass is melted from lascas or granular quartz with an impurity content < 30 ppm, the latter being by far the most important feed. Translucent to white opaque fused silica is produced from quartz sand with an impurity content of < 300 ppm. In both cases low contents of aluminum and iron impurities are essential.

A titanium content indicates the presence of submicroscopic rutile crystallites, which cause bubble problems in transparent silica glass during tube drawing. Silica glass for semiconductor uses, if not produced from high-purity silicon, must be very low in heavy metal impurities.

Well Fracturing. For hydraulic fracturing of oil, gas, or geothermal wells, a fluid with suspended quartz sand is pumped at high pressure into the well. Existing openings are enlarged and new voids are created. When the fluid is withdrawn, the remaining sand holds the fractures open. Frac sand must have >98 wt % SiO_2 and well-rounded grains to make placement easier and to provide good permeability. It must consist of single-crystalline grains which are clean and, in particular, free of adhering feldspar, clay, or carbonate minerals. The solubility in hydrochloric acid (a measure of the carbonate content) must be < 0.3 wt %. The content of soft particles must be < 1 wt %.

3. Diatomites

3.1. Introduction

The term diatomite (kieselguhr) refers to sedimentary rocks that are mainly composed of the skeletons of single- celled diatoms.

The low density, high porosity – and thus high absorption capacity for liquids – low thermal conductivity, and outstanding filtration properties make diatomite a versatile raw material [209 – 211].

Deposits with similar petrographic character or analogous physical properties, named according to their origin or area of application, include siliceous earth, "Bergmehl", "Saugschiefer", "Polierschiefer", and tripolite, not all of which are true diatomites.

The designation "tripolite" is derived from the ancient name *terra tripolitana* (after the city of Tripolis). The name referred mainly to minerals used as grinding and polishing agents, but also as lightweight building blocks. Today, the term tripolite refers to extremely fine-grained quartz pelites of inorganic origin [212].

3.2. Formation, Composition, and Quality Criteria [229 – 231]

Diatoms can be described as being almost "ubiquitous", occurring in marine, brackish, and freshwater environments.

The plant organisms possess a silicified membrane and vary in size between several micrometers and ca. 2 mm (generally 10–150 μm).

The skeletons are composed of opal-like, amorphous silica ($SiO_2 \cdot x\ H_2O$) and exhibit a wide range of porous fine structures and shapes. Including fossil forms, at least 15 000–20 000 different forms have been distinguished.

Rock-forming processes involving diatoms occurred worldwide from the Upper Cretaceous period onwards. Commercially exploitable deposits have been formed since the tertiary period.

The deposits are associated with sedimentation areas in which nutrients were abundant and the supply of silicates or dissolved silica was sufficient that a rich diatom flora developed and the frustules of the dead organisms accumulated to an appreciable thickness on the bed of the water body.

Such conditions are found worldwide, mainly in areas with volcanic activity, but also to a lesser extent in lakes with a largely decalcified environment and intensive chemical weathering of quartz sands or silicates (e.g., the German diatomite deposits) [212, 213].

Formation of diatomites of considerable thickness also occurred in marine coastal areas with continual subsidence, a periodical barrier to the open sea, and a regular supply of nutrients [214]. In addition, diatomites of brackish origin were formed in former saltwater lakes.

Important quality criteria for crude diatomite include the particle-size distribution, shape, and fine structure of the diatoms (Fig. 18). However, these can be altered with regard to their structural framework (and porosity) by calcination (see Section 3.4) [215, 216], which is important for the various applications as filtration agents. Furthermore, the chemical and mineralogical composition plays an important role, since higher contents of certain components can limit economically viable processing and refinement of the crude product.

Apart from water and organic substances the most frequent additional components of diatomites are quartz, calcium carbonate, and clay minerals.

The content of water and organic substances is only of minor significance for quality assessment, since they can be removed by drying or calcination.

Quartz sands or other rock fragments of similar particle size can be removed by air classification. In this respect, the conventional specification of the SiO_2 content of a crude diatomite is not very informative. For the assessment of a diatomite it is not the total SiO_2 content which is decisive, but the content of opal (diatom skeletons).

In contrast, the presence of fine-grained carbonates [$CaCO_3$, $CaMg(CO_3)_2$] in amounts greater than 5–10 mol % is problematic because they form complexes during processing which adversely affect the filtration properties and lower the chemical inertness.

Clay minerals restrict the range of applications, but are advantageous for the production of insulating or refractory bricks or for use as powders.

Higher iron contents, particularly as pyrite or markasite, require refinement by calcination (see Section 3.4). The color of the diatomites becomes reddish-gray or pink due to conversion into Fe_2O_3. The filtration properties are hardly influenced, whereas the use as fillers can be affected considerably by this coloration. In the lat-

Figure 18. Light micrographs of various diatomites (diatom fraction)
A), B) Lompoc, California, United States; C) Myvatn, Iceland; D), E) Munster-Breloh, Germany; F) Hetendorf/Hermannsburg, Germany; G) Neuohe/Unterlüß, Germany

ter case, a Fe_2O_3 content of > 5–6 % can already be a limiting factor.

3.3. Occurrence and Mining

Diatomite deposits are distributed worldwide. Their economic exploitability and market potential depend on numerous factors such as mining conditions, and processing and transport costs. The size and quality of the deposit, exploitation costs, transport conditions as well as the question whether the diatomite is for a domestic market or whether it is to be exported play a significant role. In 1995, the world demand for diatomite was ca. 1.2×10^6 t/a [217].

The largest diatomite deposits in the world are found in the United States in the district of Lompoc, California. These are upper Tertiary (Miocene) marine deposits with an economically exploitable diatomite thickness of ca. 300 m. In addition, large quantities of marine

and freshwater diatomites are mined in Georgia, Mississippi, Nevada, Oregon, and Washington. In 1986, the United States accounted for about one-third of world production (575 000 t), followed by Rumania, the CIS, and France, with outputs of $(246–272)\times10^3$ t (1986). The production in Rumania and the CIS is almost entirely used in the building construction industry. Further, noteworthy deposits and production sites are located in Algeria, Argentina, Australia, Brazil, Germany, Iceland, Italy, Kenya, Korea, Mexico, Peru, and Spain, whereby in several of these countries the export of diatomite is of no significance [218]. Danish "Moler" is a clay-rich diatomite (diatomaceous earth), which is produced and exported in considerable quantities (63 500–72 600 t/a). It is used predominantly for the production of insulation materials (e.g., fire-resistant insulating bricks).

The only large, economically workable diatomite deposits in Germany are freshwater formations of Pleistocene age. They are situated on the edge of the Lüneburger Heide in the area of Hetendorf/Hermannsburg, Neuohe/Unterlüß, and Munster-Breloh as well as in the Luhetal (Bispingen/Hützel/Schwindebeck). Here industrial usage began with the establishment of the first open- cast mine in 1863. Thus, German diatomite mining represents the earliest modern exploitation of this raw material. Up to World War I almost the total world requirement could be met, with an export quota of $> 30\,\%$.

Diatomite is generally mined in open- cast mines, occasionally also by subsurface or underwater mining (Myvatn, Iceland). Mining by hand is now rare (Third World countries). Almost everywhere, modern, cost-effective mining methods are used, with excavators and wheel/front loaders, and trucks or conveyor belts for transport.

3.4. Processing

Worldwide, the processing methods for crude diatomite differ only slightly from one another. The most important principle is minimization of mechanical damage to the structure of the diatom skeletons. Hollow forms should not be destroyed and pores not blocked (e.g., by sintering during calcination). The high porosity, the most important property of diatomite, must be retained. The processing steps are shown in Figure 19.

Preliminary size reduction of crude material is carried out with spiked rollers, charging boxes, or sieve kneaders to give a uniform grain size that ensures even heat transfer during further treatment. This is particularly important because of the low thermal conductivity of diatomite.

The following types of processed diatomite are produced.

Dried Diatomite [*61790-53-2*]. Depending on the climatic conditions at the production site, the crude diatomite from the deposits is either stored in the open for predrying or transported immediately to storage hoppers. Crude diatomite contains 30–65 % water, which is removed in countercurrent driers. Simultaneous grinding and drying is also practiced, whereby preheated air is blown into the grinders. However, this is only possible for crude products with a low moisture content. Drying is followed by gentle grinding and screening. Granulation gives products that are used as absorbents (e.g., for oil) or as pet litter.

If the starting material is of high purity and has a low content of organic substances, the dried diatomite can also be used as a filtration agent or catalyst support. These diatomites vary in color from white to yellowish or gray-brown, depending on their origin, and consist predominantly of amorphous silica with a low crystalline content (generally $< 3\,\%$).

Calcined Diatomite [*91053-39-3*]. To remove organic substances and alter the particle size, dried diatomite is calcined in gas- or oil-fired rotary kilns at 800–1000 °C. During calcination, the diatom frustules and their fragments are hardened and partially agglomerated by sintering. The degree of sintering can be controlled by altering the temperature and duration of the process. The diatomite is then ground and classified by cyclones and sorters into grades with different particle-size distributions (fine and medium calcined diatomites). Iron impurities, present as Fe_2O_3 after calcination, color the products pink or yellowish to dark brown.

The old-fashioned furnaces with several decks, similar to pyrite-roasting kilns, are still used to a limited extent. They have the advantage of a slow calcination process at relatively low

Figure 19. Diatomite processing

temperature which causes little damage to the structure. The kilns are loaded with moist crude diatomite, which is dried on the upper decks, calcined in the middle, and cooled on the lower decks.

Fluidized-bed drying and calcination processes were tested as early as the 1920s, but were unsuccessful due to technical problems. Nowadays modern fluidized-bed technology is also used for the processing of diatomite. Advantages include energy savings, short production times, mild treatment of the diatomite, and more compact design of the plants.

Flux-Calcined Diatomite [*68855-54-9*]. In this process, dried or calcined diatomite powder is calcined with the addition of alkaline fluxes. Sodium carbonate is generally used as flux in amounts of 1–6 %, either mixed with the diatomite before calcination or continuously added during calcination. The calcination temperature is 1000–1200 °C. The addition of sodium carbonate leads to the formation of a sodium silicate glass melt which binds the diatom frustules and their fragments into agglomerates. Since the iron contained in the diatomite is also bound, a white product is formed. The degree of agglomeration can be controlled by varying the temperature, the type and amount of flux, and the reaction time. This process is also known as activation. The high calcination temperatures in the presence of alkali lead to a partial transformation (up to 65 %) of the amorphous silica into cristobalite, a crystalline silica modification. The porosity and the specific surface area are strongly decreased. The annealing and cooling processes are followed by grinding and classification, to give white filter diatomite (the main product) and a dust-like fine fraction which is used as white filler and auxiliary.

Commercially Available Forms, Products, and Producers. Powder diatomite is sold in paper sacks containing 15–25 kg as well as loose in big-bags and silo trucks. Granulated material is available in paper or plastic sacks containing 30 kg, sometimes also in big-bags or silo trucks.

Examples of commercial products are:

Celatom (Eagle-Picher Minerals Inc., Reno, United States)

Celite (Celite Corp., Newark, United States)
Clarcel (Ceca SA, Paris, France)
Dicalite (Grefco Inc., Torrance, United States)
Fina/Optima (Meyer-Breloh, Munster, Germany)
Skamol (Skarrehage Molervaerk a/S Nykøbing, Mors, Denmark)

Table 11 lists the chemical and physical properties of several commercially available diatomites.

3.5. Analysis

Chemical and physical testing begins with the crude diatomite in the mine, continues during the individual production stages, and finishes with the test certificate of the end product. The results of the crude diatomite tests determine the working plan for the different regions of an open- cast mine.

The following analyses and tests are undertaken:

Chemical Analysis. The contents of silica, iron, aluminum, calcium, magnesium, manganese, titanium, sodium, potassium, and, depending on requirements, also other elements are determined after alkaline dissolution or acidic extraction. Filter diatomites for breweries are also tested for beer-soluble iron, calcium, and sometimes other elements [219].

Physical Tests. Water content, loss on ignition (at 1050 °C), bulk density, tapped density, pH value (10 % in water), water absorption capacity, and specific surface area are determined by conventional methods [219]. The particle-size distribution is determined by laser scattering or air-jet screening. For the fine fraction, the sedimentation method is used. The wet density is the density in g/L of a filter cake flushed with water. Since the majority of diatomite is used for filtration, the determination of the permeability is of major importance since it determines the performance and the retaining power of a filter diatomite. In general, the methods developed by the individual producers in which the rate of permeation of water is measured, are sufficient. The company CECA (France) possesses a patent for a permeameter which allows fully automatic measurement. The EBC filter is of simpler construction and allows Darcy values to be precisely measured [220]. Apart from the relative units used by the diverse producers, the Darcy has become generally accepted as the unit for the permeability of a filter agent. For filter materials with the permeability of 1 Darcy the flow rate of a liquid of viscosity of 1 mPa · s is 1 mL · s^{-1} · cm^{-2} filter area for a filter- cake thickness of 1 cm and a pressure difference of 0.1 MPa. Since the permeability can be determined rapidly, this is a suitable method for differentiating between fine, medium, and coarse diatomites [219, 221 – 223].

The amorphous silica content of a diatomite is determined by the alkali solubility. This property is of significance for catalyst diatomites, or for diatomites which serve as a silica source in cement, or as chemical reagents in other silica-containing products. The specific surface area is used to assess the porosity of a diatomite. It is generally determined by nitrogen adsorption (BET method). The degree of whiteness is measured with a leucometer.

3.6. Storage and Transport

Processed diatomite is stored in steel or stainless steel silos, mostly with a circular cross section and equipped with various discharge aids, since diatomite tends to form bridges. Material packed in sacks is stored and transported on wooden palettes in amounts of 600–1000 kg enveloped by a shrink film, and also in big-bags made from plastic- coated webbing with a capacity of 600–1500 kg. Loose material is transported in silo road vehicles or rail containers with a capacity of 30–75 m^3. The diatomite is conveyed pneumatically or with screw and vibrational conveyors.

3.7. Environmental and Health Protection

Diatomite rarely contains toxic compounds. Since, however, it can contain crystalline modifications of SiO_2 in addition to amorphous silica, dust safety measures are of special significance. This is especially true of white activated

diatomites, which can contain up to 65 % crystalline cristobalite. The MAK value for uncalcined diatomite is 4 mg/m^3 and for calcined diatomite, 0.3 mg/m^3. The TLV for uncalcined diatomite is 10 mg/m^3. The International Agency for Research on Cancer (IARC) published a monograph concerning crystalline silica in 1987 [224]. This summarizes the research results concerning the influence of crystalline silica on humans and concluded that apart from causing silicosis it may also cause cancer (see also Chap. 8). Hence, crystalline silica is classified in group 2 A. As a result of this, the diatomite producers founded the International Diatomite Producers Association (IDPA), whose aims include informing personnel working in the diatomite industry and the consumer about these hazards, and to ensure adherence to the work protection regulations by increasing the information available [225, 226]. The regulations of individual countries concerning the handling of dusts containing crystalline silica differ widely:

United States: 29th Federal Statute book 1910.1000 from 19. 01. 1989, which classifies crystalline silica as a hazardous substance and specifies tolerance levels.

EC: Directive 67/548/EEC from 18. 09. 1979 concerning the classification, packaging, and labeling of hazardous substances.

United Kingdom: Control of substances which damage health No. 1857 from 1988.

Germany: UBG 119–4.86 Quartz: protection against dust dangerous to health; UBG 100–4.85, rule G.1.1.: concerning the health precautions; GefStoffV 8.86: labeling regulations.

France: No. 50.1289 from 16. 10. 1950 changed into No. 63 576 from 11. 06. 1963 concerning medical precautions against occupational silicosis. No. 11 453 from 19. 07. 1982 determines the dust concentration in the air of the work place. No. 87–200 from 25. 03. 1987 regulates the content of safety data sheets for dangerous substances. L 231–6 from 10. 10. 1983 lists dangerous substances and determines the packaging and labeling regulations.

Spain: from 27. 11. 1985 classification and labeling of dangerous substances.

Italy: No. 256 from 29. 05. 1974, No. 927 from 24. 11. 1981, No. 141 from 20. 02. 1988 concerning the classification, packaging, and information for hazardous materials.

3.8. Uses

The main uses of diatomite are the following: 60 % of world production is used as a filtration agent; ca. 25 % as filler diatomites, including carrier materials; and ca. 15 % for other uses.

Filtration Agents. Diatomite is used in both pressure and vacuum filters of various designs. Fine, medium, and coarse diatomites, as well

as mixtures thereof, are employed, depending on the desired clarity and flow rate [227]. Coarse diatomites are used for precoat filtration in pressure filters in amounts of ca. 1 kg/m^2 of filter area. Fine and medium diatomites are added to the slurry to be filtered, usually in amounts of 100–200 g/m^2 filter area (→ Filtration, Chap. 11). For use as filter aids diatomites must fulfil the following requirements:

1) Good preservation of the diatom structure
2) Optimal particle-size distribution
3) Low content of soluble components
4) High volume and therefore high capacity for materials causing turbidity
5) Formation of filter cakes with high permeability, low compressibility, and low tendency to form cracks

The most important uses of diatomite are for the filtration of beer, wine, fruit juice, sugar cane juice, swimming pool water, solvents for chemical cleaning, wastewater, varnishes, and paints etc. Large quantities of diatomite are used for the production of cellulose-based filter beds, filter candles, and special filter papers.

Fillers. Diatomite is used as filler and auxiliary, for example, to modify the rheological properties of polymers. It increases the thermal stability of bitumen, the Shore A hardness of silicone rubber, and is a reinforcing filler in plastics, rubber, and adhesives. Dust-like, white, activated diatomite is used as a delustering agent, for adjusting the viscosity of paints, and as an antiblocking agent for plastic films.

Insulators. Loose diatomite has long been used for insulating double-walled kilns made from fireclay bricks, as well as for producing insulating sheets and bricks. Danish Moler is especially well suited for producing insulating bricks, since its clay content functions as a ceramic binder. In the VSI process (vacuum super insulation), a special form of diatomite acts as a supporting and insulating layer in double-walled elements that contain a high vacuum. Thus, extremely high insulation values are achieved. The VSI process is being tested for long-distance heat transport.

Absorption Agents. Due to their high capacity for liquids, diatomites are used to produce gas purification agents as well as absorption agents such as cat litter and drying agents. Diatomite is also used to ensure the flowability and to prevent clotting of foodstuffs, fire extinguisher powders, and seeds.

Other Uses. Diatomite serves as a fine scourer in polishes and cleaners such as car polishes, toothpastes, and silver polishes. Diatomite is employed as a catalyst support, for the production of pyrotechnics and matches, as a packing material for the transportation of hazardous liquids, and for the filling of acetylene bottles. In some countries it is used as the silica source for the production of cement and calcium silicate.

3.9. Recycling

Attempts to regenerate diatomite have been undertaken for many years [228]. This is only economically viable for diatomites loaded with organic residues, which can be purified by leaching or calcination. In Germany, the company Tremonis operates a thermal process for recycling filter residues from breweries. The flow diagram of the plant is shown in Figure 20. The regenerated diatomite is classified as fine diatomite. It is added to the fresh diatomite for beer filtration in quantities of up to 50 %.

4. Colloidal Silica

4.1. Introduction

Silica sols are stable disperse systems in which the dispersion medium (or continuous phase) is a liquid and the disperse or discontinuous phase is silicon dioxide in the colloidal state of subdivision. This state comprises particles with a size sufficiently small (< 1 µm) not to appear affected by gravitational forces but sufficiently large (> 1 nm) to show marked deviations from the properties of typical solutions (see → Colloids, Chap. 4).

The limits given for the colloidal size range are not rigid since they depend to some extent on the properties under consideration [232].

Silica sols are commonly known as *colloidal silica.* Although the ultimate particles that constitute silica gels, xerogels, cryogels, aerosols,

Figure 20. Flow sheet of thermal diatomite regeneration (Tremonis GmbH, Dortmund, Germany)

and pyrogenic (fumed), precipitated, and coacervated silica have lost their mobility by aggregation. They are also in the colloidal range of particle size and are therefore known as colloidal silicas. However, in this chapter the terms silica sol and colloidal silica are used as synonyms. Figure 21 illustrates the relationship between silica sols, gels, and powders [233].

In commercial silica sols the disperse silica is amorphous and the dispersion medium in most cases is water (aquasols or hydrosols). Dispersions in organic solvents are also commercially available (organosols). Silica sols are fluid and stable toward gelation and settling. Most commercial sols are close to monodisperse and consist of dense discrete spheres with a diameter range between ca. 4 or 5 nm and 100 nm. Also commercially available in the form of sols or powders are grades with particles between 0.1 and ca. 1.5 µm. Particle size, particle-size distribution, and concentration of solids determine the appearance of sols. Silica sols look milky if the particle size is large and the concentration is high, opalescent if the size is intermediate, or clear and almost colorless if the particles are of the smallest size range.

Although there are earlier references to what are now known as silica sols, it was Graham [234] who coined the term *colloidal* in 1862 to refer to products such as the one he obtained by reacting acid with silicate and removing the electrolytes by dialysis. Stable and relatively concentrated silica sols were not available until the 1930s when I. G. Farbenindustrie first made 10 wt % ammonia-stabilized silica sols [235]. However, the real breakthrough in colloidal silica technology came in 1941 when Bird [236] patented a process for removing the alkali from a dilute solution of sodium silicate by ion exchange. The next landmark in the development of concentrated silica sols was the first process for making colloidal silica particles of uniform and controlled size reported in 1951 by Bechtold and Snyder [237].

By 1990 colloidal silica constituted a growing market valued at an estimated \$ 50×10^6 in North America [238] and € 15×10^6 in Europe [239]. Applications of silica sols are based on characteristics such as particle size, high specific surface area that gives them good binding ability, stability towards gelation and settling, and surface properties. These characteristics enable

Figure 21. Formation of silica sols, gels, and powders by silica monomer condensation–polymerization followed by aggregation or agglutination and drying [233]
Growth of nascent colloidal particles with decrease in numbers occurs in basic solutions in the absence of salts. In acid solutions or in the presence of flocculating sols the colloidal silica particles form gels by aggregation into three-dimensional networks. Aerogels are made by drying wet gels under supercritical conditions, that is, above the critical temperature T_C and critical pressure of the liquid. Cryogels are made by drying wet gels below the melting temperature T_M of the liquid. Fumed or pyrogenic silicas are formed at high temperature by flame oxidation–hydrolysis of silicon halides

colloidal silica to be used in a wide variety of applications. Major uses are in investment casting, silicon-wafer polishing, and fibrous ceramics.

4.2. Structure of Colloidal Silica Particles

The building block of silica is the SiO_4 tetrahedron, four oxygen atoms at the corners of a regular tetrahedron with a silicon ion at the central cavity or centroid [240] (see Chap. 1). The oxygen ion is so much larger than the Si^{4+} ion that the four oxygens of a SiO_4 unit are in mutual contact and the silicon ion is said to occupy a tetrahedral hole [240]. In amorphous silica the bulk structure is determined, as opposed to the crystalline silicas, by a random packing of $[SiO_4]^{4-}$ units, which results in a nonperiodic structure (see Fig. 22). As a result of this structural difference amorphous silica has a lower density than the crystalline silicas: 2.2 g/cm^3 versus 3.01, 2.65, 2.26, and 2.21 g/cm^3 for coesite, α-quartz, β-tridymite and β- cristobalite, respectively.

Figure 23 represents a two-dimensional random network of a dehydrated but fully hydroxylated amorphous silica particle.

Figure 22. Tetrahedral configuration of crystalline (A) and amorphous (B) silica; (C) represents a silicon atom (filled circle) coordinated by four oxygen atoms (large atom spheres) [241]

Figure 23. Two-dimensional random network of a dehydrated but hydroxylated colloidal silica particle
Four rules apply [242]: each oxygen ion is linked to no more than two silicon ions. The coordination number of oxygen ions about the central Si cation is 4 (the fourth oxygen not represented in the figure is directly above or below the Si cation). Oxygen tetrahedra share corners, not edges or faces. At least two corners of each tetrahedron are shared. Since the particle is fully hydroxylated each surface Si ion is bonded to one or two hydroxyl ions: the silanol number is 4.6 OH/nm^2. Depending on the method of formation some internal Si ions may be linked to hydroxyl ions. Surface of occluded alkali-metal ion impurities may replace surface or internal protons. Aluminum ion impurities or added modifiers may replace internal or surface tetrehedral Si. The particle surface may be esterified, silanized (silylated), or ion exchanged. The concentration of OH groups on the surface decreases monotonically with increasing temperature when silica is calcined

Impurities such as Na, K, or Al, picked up during synthesis of silica aquasols in alkaline media, may be occluded inside the colloidal particles, replacing internal silanol protons (Na, K) or forming isomorphic tetrahedra (Al) with an additional negative charge on the surface or inside the particles (see Fig. 24). Sols obtained by hydrolysis of alkoxysilanes or by dispersion of pyrogenic silica in water or an organic solvent are pure and substantially free of alkali metals or aluminum.

Figure 24. Internal structure of an amorphous silica particle showing an internal silanol group and occluded Na and Al ions

Many of the adsorption, adhesion, chemical, and catalytic properties of colloidal silica depend on the chemistry and geometry of its surface. In 1934 Hofman [243] postulated the existence of silanol (Si–OH) groups on the silica surface. It is now generally accepted that surface silicon atoms tend to have a complete tetrahedral

configuration and in an aqueous medium their free valence becomes saturated with hydroxyl groups forming silanol groups. Under appropriate conditions, silanol groups in turn may condense to form siloxane bridges: ≡Si−O−Si≡.

In the meantime most of the following postulated groups have been identified on the surface or in the internal structure of amorphous silica (see Fig. 25).

1) Single silanol groups, also called isolated or free silanol groups
2) Silanediol groups, also called geminal silanols
3) Silanetriols, postulated but existence not yet generally accepted [244]
4) Hydrogen-bonded vicinal silanols (single or geminal), including terminal groups
5) Internal silanol groups involving OH groups, sometimes classified as structurally bound water (see Fig. 25 B)
6) Strained and stable siloxane bridges
7) Physically adsorbed H_2O, hydrogen-bonded to all types of surface silanol groups (see Fig. 25 B)

Silanol groups are formed on the silica surface in the course of its synthesis during the condensation polymerization of $Si(OH)_4$ or by rehydroxylation of thermally dehydroxylated silica with water or aqueous solutions.

The silanol groups on the silica surface may be classified according to their nature, multiplicity of sites, and type of association [245].

An isolated silanol has an OH group sufficiently remote from neighboring hydroxyl groups that hydrogen bonding cannot occur (≥ 0.33 nm). A silicon site of this kind is designated as Q^3 in NMR Q^n terminology, where n is the number of bridging oxygens bonded to the central silicon. The isolated silanol shows a sharp band at around 3750 cm^{-1} in the IR spectrum [246, 247].

Geminal silanols are silanediol groups located on Q^2 silicon sites. Their existence was postulated by Peri [246 – 248] but only confirmed experimentally with the advent of solid-state ^{29}Si cross-polarization magic angle spinning nuclear magnetic resonance (CP MAS NMR) [249].

Vicinal or hydrogen-bonded or associated silanols are SiOH groups located on neighboring Si atoms such that the OH - - - O distance is sufficiently short for hydrogen bonding to occur. Hydrogen bonding causes a reduction in the O−H stretching frequency, the magnitude of which depends on the strength of the hydrogen bond and thus on the O−H−O distance [250]. The characteristic IR band of vicinal groups occurs at about 3660 cm^{-1} [251].

Geminal Q^2 silanol sites bonded to a neighboring Q^3 silicon through a single siloxane bridge also result in a hydrogen-bonded pair. The remaining OH group experiences very weak hydrogen bonding.

Silanol groups are also found within the structure of the colloidal particles. These groups are designated as internal silanols and in some cases are erroneously referred to as structurally bound water. The concentration of internal silanol groups depends on the synthesis temperature and other variables.

Surface and internal silanol groups may condense to form siloxane bridges. Strained siloxane bridges are formed on the hydroxylated silica surface by thermally induced condensation of hydroxyl groups up to about 500 °C. At higher temperature, the strained siloxane bridges are converted into stable siloxane bridges [250].

Strained siloxane groups undergo complete rehydroxylation on exposure to water in a matter of hours or a few days, depending on type of silica powder and conditions of exposure [251]. Stable siloxane groups are rehydroxylated at a

Figure 25. A) Possible types of silanol groups and siloxane bridges occurring on the surface of colloidal silica particles Characteristic bands in the infrared spectrum and Q^n site designation is included (n is the number of bridging oxygens bonded to the central silicon atom); B) Surface bound water and internal silanols

Figure 26. Modified colloidal silica surface

slower rate. For example, a wide-pore sample of 340 m^2/g calcined in air at 900 °C required five years of contact with water at room temperature for complete rehydroxylation [252].

Surface silanol groups are the main centers of adsorption of water molecules [252]. Water can associate by hydrogen bonding with all types of surface silanols, and in some cases with internal silanol groups.

Figure 27. Silylated and esterified silica surface

Surface silanol groups of silica aquasols stabilized in an alkaline medium exchange protons for ions such as Na^+, K^+, or NH_4^+ (Fig. 26). The surface silanol groups can be esterified, as in the case of silica organosols, or silanized (silylated) (Fig. 27). Derivatization, that is modification of the silica surface, is the basis for the use of silica in analytical and process chromatography.

The surface charge of pure silica aquasols is negative at a pH higher than ca. 3. The isoelectric point (IEP) is ca. 2. The IEP can be shifted by partial substitution of surface silicon groups by tetrahedral aluminum (see Fig. 26). In this way the pH range of stability of aquasols may be varied. The surface charge can be reversed by adsorption of octahedral aluminum ions such as those present in basic aluminum chloride [253] (Fig. 26). Aquasols obtained in this manner are commercially available in various particle sizes and concentrations as *positive sols.*

The concentration of silanol groups on the silica surface α_{OH} expressed as the number of OH groups per square nanometer is the silanol number [252]. For a dehydrated but fully hydroxylated amorphous colloidal silica powder α_{OH} is 4.6 [252].

The threshold temperature corresponding to the completion of dehydration, that is removal of physisorbed water from the silica surface, and the beginning of dehydroxylation by condensation of surface OH groups, is estimated to be 190 $\pm$ 10 °C [252].

The concentration of OH groups on the surface decreases monotonically with increasing temperature when silicas are heated under vacuum (Fig. 28). Most of the physisorbed water is

Figure 28. Effect of temperature on silanol groups on the surface of colloidal silica

removed at about 150 °C. At 200 °C all the water from the surface is gone so that the surface consists of single, geminal, vicinal, and terminal silanol groups and siloxane bridges. At ca. 450–500 °C all the vicinal groups condense yielding water vapor and only single, geminal, and terminal silanol groups and strained siloxane bridges remain. The estimated ratio of single to geminal silanol groups on the surface is 85/15 [252] and is believed not to change with temperature, at least up to ca. 800 °C. Internal silanols begin to condense at ca. 600–800 °C and in some cases at lower temperatures. Complete evolution of internal silanols occurs at higher temperatures. It appears that at temperatures from ca. 800 °C to ca. 1000–1100 °C, only isolated (single) silanol groups remain on the silica surface.

At a sufficient surface concentration, the OH groups make the silica surface hydrophilic, whereas a predominance of siloxane groups on the silica surface makes the surface hydrophobic.

4.3. Physical and Chemical Properties

Most commercial silica sols consist of dense, discrete, spheroidal particles typically 4–60 nm in diameter and amorphous to X-ray or electron diffraction. Because they are amorphous the silica particles are only slightly soluble in water (100–150 ppm at 25 °C and pH 2–8) and insoluble in alcohol or in inorganic acids except HF. They are soluble in organic bases such as tetramethylammonium hydroxide, forming water-soluble quaternary ammonium silicates, and, as opposed to crystalline silicas, are very soluble in hot sodium hydroxide solution. Specific surface areas vary with particle size, and for the common grades of silica sols are between 50 and 750 m^2/g. Less typical grades have particle diameters between 60 nm and 1.5 µm with specific surface areas much lower than 50 m^2/g, depending on their particle diameter. The specific surface area A in m^2/g of a system made of solid monodisperse amorphous silica spheres with a smooth surface and bulk density 2.2 g/cm^3 is:

$$A = 6000/2.2\,D$$

where D is the diameter of the spheres in nanometers.

Table 12 lists typical properties of representative commercial silica aquasols. The table also shows the dependence of relative density and viscosity on the silica content. Viscosity also depends on particle size and degree of cross-linking of the particles. In 30 % silica aquasols it is generally < 10 mPa · s.

Silica sols obtained by dispersion of pyrogenic silica powders generally differ from those

Table 12. Typical properties of commercially available negative and positive silica aquasols* [254]

synthesized in solution. The dispersion of pyrogenic silica to a sol of separate, discrete ultimate units is difficult, even using intense mechanical shearing forces, due to the extensive coalescence of the particles. Thus, the disperse product consists mainly of short chain-like aggregates made up of small silica particles (see Section 4.5). Typical properties of commercial sols made in this way are listed in Table 13.

Table 14 lists particle size, silica concentration, and viscosity of commercially available organosols.

Silica sols are said to be stable because they do not settle or aggregate for long periods of time. Aggregation and rate of settling, as well as color, appearance, viscosity, density, growth, and solubility in water are functions of particle size. At optimum pH, electrolyte and SiO_2 concentration, aquasols of particle size 4 to ca. 40 nm are extremely stable to settling, whereas aquasols of particle size larger than ca. 60 nm tend to show some settling in a period of months. Particles larger than 100 nm settle on standing, leaving a clear upper layer after a few weeks or days. When the concentration of the silica aquasol is $>$ 10–15 wt % the particle size can be judged visually by the turbidity. If the particles are smaller than ca. 7 nm in diameter the sol is almost as clear as water; from 10–30 nm there is a characteristic opalescence or translucency when seen in bulk; above 40 or 50 nm the appearance is white and milky [235].

Commercial silica aquasols are stabilized near the optimum pH and are concentrated to the maximum concentration permitted by the particle size [257]: ca. 15 wt % for 4–5 nm, ca. 30 wt % for 8–9 nm, ca. 40 wt % for 14 nm, ca. 50 wt % for 22 nm (Fig. 29).

Figure 29. Maximum concentration versus particle size in stable aqueous silica sols at about pH 9.5
a) Concentration in wt %; b) Concentration in grams SiO_2 per 100 mL; c) Volume fraction of SiO_2 ($\times$100) [257]

When silica sols are gelled, dried, or frozen the original degree of dispersion cannot be restored without dissolution of the interparticle bonds that develop. Special dried grades are made of particles with the surface esterified with primary or secondary C_2–C_{18} alkoxy groups. These are organophilic and hydrophobic and can be dispersed in organic solvents or in organic products such as elastomers or plastics. Silica

sols surface-modified with organic base cations such as $(CH_3)_4N^+$ can be evaporated to a dry powder that disperses spontaneously in water [258].

4.4. Stability

Three types of stability may be distinguished in colloidal systems [259]:

1) Phase stability, analogous to the phase stability of ordinary solutions.
2) Stability to change in *dispersity* [259], that is particle size or particle-size distribution. For example, commercial concentrated silica sols, normally said to be 3 or 4 nm in particle size usually grow within hours or a few days to 5 nm or more on standing at room temperature. Concentrated sols normally labeled 7 nm, if not substantially homodisperse, may grow within months to 8–9 nm. This ripening effect also occurs for larger particle sizes, although at a much slower rate. A concentrated silica sol of 14 nm particle size was found to grow to 17 nm in twenty years at room temperature [260].
3) *Aggregative stability* [259], the central issue in colloidal silicas, and for that matter in colloidal systems in general. In this case *colloidally stable* means that the colloidal particles do not aggregate at a significant rate [232]. The term aggregate is used to describe the structure formed by the cohesion of colloidal particles [232].

Two mechanisms of sol stabilization are generally believed to exist: electrostatic stabilization and steric stabilization (see → Colloids,

Chap. 5). Electrostatic stabilization is based on an interplay of electrostatic repulsion between electrically charged colloidal particles and van der Waals forces of attraction between particles. The DLVO theory (Derjaguin, Landau, Verwey, and Overbeek) constitutes an attempt to describe quantitatively this interplay (see → Colloids, → Colloids). Steric stabilization is generally caused by long-chain molecules or macromolecules adhering on the colloidal particle surface (e.g., by grafting or by physical adsorption), thus preventing the particles from aggregating [261].

Colloidal silica particles aggregate by linking together and forming three-dimensional networks as is the case in gelation, coagulation or flocculation, or by coacervation [262]. In coacervation the silica particles are surrounded by an adsorbed layer of material which makes the particles less hydrophilic but does not form bridges between particles [263].

When a sol is gelled it first becomes viscous and then develops rigidity, filling the volume originally occupied by the sol. On the other hand when a sol is coagulated or flocculated, a precipitate is formed that settles out. A simple way to differentiate between a precipitate and a gel is that a precipitate encloses only part of the liquid in which it is formed [262].

Stability of silica aquasols against irreversible gelation decreases with increasing silica concentration, increasing electrolyte concentration of the aqueous medium, decreasing particle size, and increasing temperature. Water-miscible organic liquids have a similar destabilizing effect on silica aquasols as added electrolyte. The variation of stability as a function of pH and salt concentration is shown in Fig. 30 [264].

According to Iler [265] the basic step in gel formation is the collision of two silica particles with sufficiently low charge on the surface that they come into contact so that siloxane bonds are formed, holding the particles irreversibly together. Formation of this linkage requires the catalytic action of hydroxyl ions (or, as interpreted by some, the dehydration of the surface of particles at higher pH). This is evidenced by the fact that the rate of gel formation in the pH range 3–5 increases with pH and is proportional to the hydroxyl concentration.

Above pH 6, scarcity of hydroxyl ions is no longer the limiting factor on the rate of gelling. Instead, the rate of aggregation decreases because of fewer collisions between particles owing to the increasing charge on the particles and thus decreases with higher pH. Lines in Figure 30 schematically represent the increase in the catalytic effects of hydroxyl ions with increasing pH, and the decrease in the number of effective collisions between particles with increasing pH and particle charge. The net result of these two effects is a maximum in rate of gelling at around pH 5. In the pH range 8–10, sols are generally stable in the absence of salts.

There is also a region of temporary stability at about pH 1.5. Below pH 1.5, traces of HF catalyze aggregation and gelling [266]. In essentially all silicas, traces of fluoride ions, even less than 1 ppm, are present so that the concentration of HF increases with increasing acidity. The fluoride effect is influenced by the aluminum impurities present, since these inactivate some of the fluoride by forming complex ions such as AlF_6^{3-} and other species [267]. However, the gelling rate increases as the pH falls below 3 even when fluorine is absent.

Once the siloxane bonds have formed between particles, further deposition of silica occurs at the point of contact owing to the negative radius of curvature. This occurs rapidly above pH 5, and is slow at pH 1.5.

Since the curves shown in Fig. 30 are constructed on the basis of irrefutable experimental evidence it is quite obvious that silica sols do not conform to the DLVO theory as originally formulated. For example, the DLVO theory predicts minimum stability at the point of zero charge (pH 2–3), whereas the experimental curve shows metastability. Also, the plot shows minimum stability in the pH range 4–7, whereas the DLVO theory predicts a continuous increase in stability in this pH range. Research is being conducted to study the possibility of modifying or amending the DLVO theory or developing a new theory of stability applicable to silica sols.

In addition to common electrolytes such as NaCl, NH_4Cl, and KF, silica aquasols are destabilized and gelled by positively charged sols. When frozen at ca. 0 °C or lower, silica sols gel irreversibly. Long-chain nitrogen bases are effective flocculating agents for silica aquasols that form planar rather than spheroidal aggre-

Figure 30. Effect of pH in the colloidal silica–water system [258]

gates. Flocculation may also result from the addition of water-miscible organic solvents to alkali-stabilized silica sols.

Commercial silica aquasols are stabilized at pH 8.5–10.5 by alkalies, usually sodium hydroxide. Ammonia or potassium hydroxide is used when the presence of sodium ions is undesirable.

Surface-modified silica aquasols made by coating the silica particles with tetrahedral aluminum (e.g., sodium aluminate) are much more stable towards gelling in the pH range 4–6 where unmodified sols gel most rapidly. Silica sols modified in this manner are also less sensitive to salts [268].

Coating the negative silica surface with oxides of polyvalent metals such as Al, Cr, Ga, Ti, and Zr reverses the charge of the surface to produce positive aquasols stable at acid pH values [269]. An important characteristic of these sols is that they can be dried and repeptized. Only polymeric hydrolyzed species such as $Al_2(OH)_5Cl$ and not the single Al^{3+} ion can cause charge reversal of silica sols [270, 271].

4.5. Production

The classic silica aquasols of particle size 5–100 nm are prepared by nucleation, polymerization, and growth in aqueous systems. The particle-size range can be extended to at least 300 nm by autoclaving. Silica organosols can be obtained by transferring aquasols to an organic solvent or by hydrolysis of a silane precursor in a mixture of alcohol/ammonia and sufficient water [272] followed by transfer to the solvent.

The most important processes to make silica sols are based on neutralization of soluble silicates with acids, ion exchange, hydrolysis of silicon compounds, dispersion of pyrogenic silica, electrodialysis, dissolution of elemental silicon, and peptization of gels [273].

Most commercial silica sols are prepared by ion exchange of dilute solutions of sodium silicate. Several methods have been proposed since the pioneering work of Bird [236], Bechtold and Snyder [237], Alexander [274], Atkins [275], Wolter and Iler [276], Mindick and Reven [277], and Dirnberger [278]. Sodium silicate can be deionized in a batch operation by adding simultaneously a dilute solution of sodium silicate and a cationic ion-exchange resin in the hydrogen form to a vigorously stirred weakly alkaline aqueous reaction medium in the pH range around 9, at 60–100 °C [276] (Fig. 31). Under these conditions the system is stabilized against aggregation and the original silica nuclei grow while the sol concentration in-

Figure 31. Ion-exchange process for silica aquasols

creases to about 10–15 % silica. Rate of addition, pH, and temperature determine the particle size and quality of the sol.

After separation of the resin for regeneration, more sodium silicate is added to adjust the SiO_2/Na_2O ratio as needed for further stabilization of the sol. The product is filtered and concentrated to the desired level. Sols of small particle size, such as 7 nm, may be used as "heels" to build up the particle size, for example, to 14 or 22 nm.

An alternative method of deionizing sodium silicate is to pass a relatively dilute solution through a bed of ion-exchange resin to produce a sol which is then stabilized with alkali and concentrated. The particles grow during evaporation. The addition of further deionized sol to the evaporating liquid allows silica to build up on previously nucleated particles resulting in larger particle size.

Silica sols can also be made by dispersion of pyrogenic silica in water or in an organic solvent. Commercial pyrogenic silica, also known as fumed silica or aerosil, is made from silicon tetrachloride at high temperatures by a flame hydrolysis–oxidation process (see Chap. 6) [279]. The product is a highly aggregated silica powder. Pyrogenic silicas can be partially disagregated and dispersed to obtain aquasols or organosols of relatively high silica concentration. The silica units in this case consist mainly of short chain-like aggregates composed of silica particles ca. 7–25 nm in diameter.

Monodisperse silica sols of exceptionally large particle size can be prepared by hydrolysis of tetraethoxysilane (TEOS) in a basic solution of water and alcohol [272]. It is claimed that the largest mean particle size that can be produced with TEOS is about 0.8 µm [280]. However, particles up to ca. 2 µm can be made by using tetrapentoxysilane [279], performing the reaction at low temperature [281], or growing the particles by adding more alkoxide after the particles have formed [281]. Wolf [282] has adapted the TEOS method to produce commercial quantities of silica sols.

Viable processes for making commercial silica sols are based on the electrodialysis of sodium silicate solutions to continuously remove sodium ions until a sol is obtained. In the Iler [283] and the Bergna [284] processes there are three compartments separated by two parallel, closely spaced cation-exchange membranes between which the process or "heel" solutions of silica sol in dilute Na_2SO_4 as a conducting electrolyte are rapidly circulated at a specified temperature. Sulfuric acid is circulated in the anode compartment and an alkali in the cathode compartment where sodium hydroxide is generated. Dilute sodium silicate is fed to the third compartment to form SiO_2 by electrolysis. The silica or polysilicic acid that forms is deposited on the silica particles of the "heel" solution, and circulation of the solution is continued until the desired particle size is achieved. Sols of 25 % silica, 15 nm particle size can be prepared directly. Concentrated sols of ca.8 nm particle size with very narrow particlesize distribution can be obtained by seeding in a first step at a lower tem-

perature and raising the temperature in a second step to accelerate silica deposition [284].

Among the advantages of the electrodialysis process are that alkali, oxygen, and hydrogen can be recovered, and that there is much less salt-containing wastewater to be disposed of. The disadvantages of the process are higher electrical and maintenance costs.

4.6. Analysis and Characterization

Characterization of silica sols is aimed at identifying:

1) Physical and chemical properties of the sol
2) Compatibility and stability properties of the sol
3) Purity of the sol
4) Use-related characteristics

Selection of silica sols for commercial uses is commonly based on the nature of the liquid phase (water or organic solvent), particle size, particle-size distribution, degree of aggregation, pH, silica and counterion (stabilizing agent) concentration, viscosity, relative density, and specific surface area.

However, to fully understand and predict the behavior of silica sols and derived powders, it is necessary to determine other characteristics such as particle and particle surface structure; chemical composition including total carbon, organic carbon, soluble salts of alkali metals, total solids, nonsiliceous ash, and trace metals (especially Al and Fe); and physical properties such as turbidity, percent S (the percent by weight of silica in the dispersed phase of a silica sol [285]), refractive index, light scattering, sedimentation rate by ultracentrifugation, porosity, rate of dissolution of the particles, and coalescence factor of derived powders (the coalescence factor is the percent silica that must be dissolved to restore the light transmission under standard conditions of a silica powder redispersed in water [286]). In addition, most manufacturers of colloidal silicas use special tests for specific uses.

A new concept in the characterization of colloidal silica is the application of the fractal approach to sols and gels. The concept of fractal geometry, developed by Mandelbrot [287] in the early eighties, provides a way of quantitatively describing the average structure of certain random objects. For the application of the fractal concept to colloidal silica, see [241, 250].

Most of the methods utilized to characterize silica sols for commercial uses and for research purposes are listed below:

Chemical analysis
% total solids
% and nature of liquid phase
% SiO_2
% NH_4
SiO_2/Na_2O weight ratio
Sulfates as % Na_2SO_4
Chlorides as % NaCl
Carbon including CO_2
Organic carbon
Metals including Al and Fe
Nonsiliceous ash

Physical characteristics
pH
Relative density
Viscosity
Turbidity
Refractive index
Light scattering
Specific conductivity

Particle characteristics
Size and size distribution
Specific surface area (Sears titration of the sol [260] and BET measurement of the derived dried powder)
Porosity
Degree of aggregation
% S (silica in the dispersed phase)
Turbidity
Viscosity
Surface charge
Electrokinetic potential (isoelectric point)
Silanol number

Stability tests
Gelation tests
Flocculation tests

The following methods are used to measure the particle size and particle-size distribution of silica sols [288 – 291]:

Chemical methods
Gas adsorption (e.g., BET) [288]
Titrations (e.g., Sears titration) [289]
Rate of dissolution of particles [290]

Instrumental methods [291, 292]
Transmission electron microscopy (TEM)
Dynamic light scattering: photon correlation spectroscopy (PCS): Malvern Correlator, Coulter N4 Analyzer
Sedimentation field flow fractionation (SF3)
Size-exclusion chromatography (SEC)
Hydrodynamic chromatography
Capillary zone electrophoresis (CZE)

Methods for characterizing the surface of colloidal silica particles are [250, 292]:

Spectroscopy
FTIR (Fourier transform infrared spectroscopy)
DRIFT (diffuse reflectance)
Probe molecule adsorption by DRIFT
^{29}Si CP MAS NMR spectroscopy (^{29}Si cross-polarization magic angle spinning nuclear magnetic resonance spectroscopy)
^{1}H MAS NMR spectroscopy
^{1}H CRAMPS (combined rotation and multiple pulse spectroscopy)
SIMS (secondary ion mass spectrometry)
SNMS (sputtered neutrals mass spectrometry)
EXAFS (extended X-ray absorption fine structure spectroscopy)
XPS (X-ray photo emission spectroscopy) (ESCA)

Thermal and calorimetric methods
Microcalorimetry
TGA (thermogravimetric analysis)
DTA (differential thermogravimetric analysis)
DSC (differential scanning calorimetry)
Thermoporometry

Heterogeneous isotopic exchange
Use of deuterated and tritiated substances combined with mass spectrometry, IR, and ^{1}H NMR

Adsorption and wetting
Adsorption of gases and vapors combined with IR, microcalorimetry
Fractality (fractal dimension)
TPD (temperature programmed desorption) of adsorbed substances (NH_3, pyridine, etc.) coupled with spectrometry and IR
Adsorption of bases (*n*-butylamine) using Hammett or arylmethanol indicators
Wetting with liquids

Microscopy
TEM (transmission electron microscopy)
SEM (scanning electron microscopy)
FESEM (field emission scanning electron microscopy)

Scattering
SAXS, SANS (small angle X-ray and neutron scattering)

Chemical methods
Use of chemically reactive substances: chlorine, metal halides, Grignard compounds, reactive chloro- and alkoxysilanes

4.7. Uses

This section gives a brief description of the major industrial uses of silica sols. The many minor uses are too numerous to be discussed here.

Colloidal silica is widely used as a binder in the modern version of the ancient lost wax process for casting metal [293]. In this process, known as *shell investment casting,* a wax original or a cluster of originals is dipped in a slurry of colloidal silica and refractory powder. Excess slurry is drained from the wax parts and a dry refractory sand is applied to the wet surface. The coating is then allowed to dry. These coating steps are repeated until a ceramic shell of sufficient thickness, usually about 5–10 mm, is built up around the wax.

The wax is then melted out, and the ceramic shell fired to increase its strength and to remove the last traces of wax. Molten metal is poured into the hollow left by the wax. When the metal has cooled, the shell is broken away and the metal, now an exact replica of the original wax shape, is recovered.

This process is widely used to produce jet engine components as well as a large number of other metal parts. The tolerances of the finished casting can be held very close to the final requirements, thus minimizing the need for additional finishing operations.

Refractory fibers can be bonded with colloidal silica to give *insulators* that have excellent high-temperature resistance. The process is similar to papermaking in that the fibers are suspended in water and the mixture passed through

a screen which retains the fibers and allows the water to pass through and be recycled. The thickness of the fiber mat can vary from 0.1–10 cm depending on the insulating properties required. The screen is often contoured to give a shaped insulator. Usually, vacuum is used to assist the flow of water through the screen.

Colloidal silica is used two ways in this process. It is often used in small quantities together with starch in the original fiber suspension to help flocculate the fibers and the starch for better drainage and retention on the screen. The starch acts as the binder in the unfired or green state. Additional colloidal silica is often added to the final shape to stiffen and strengthen it and provide additional strength when the part is heated and the starch is burned out.

More recently, colloidal silica has been applied to the *papermaking* process itself. By adding small amounts of high surface area colloidal silica and a high molecular mass starch to the paper pulp, drainage rates and fiber and filler retention are improved. This allows for higher filler loadings, use of more recycled pulp, and in some cases, higher production rates [294 – 298].

Small amounts of colloidal silica increase the coefficient of friction of surfaces. One of the earliest uses of colloidal silica was to diminish the slipperiness of floor waxes while not affecting their gloss [299, 300]. It is widely used to improve the frictional character of paper and boxboard, which facilitates handling and reduces breakage resulting from falling boxes [301].

Carpets and other surfaces coated with colloidal silica resist soiling because the colloidal silica occupies the sites which would most likely retain visible soil.

The strength and adhesion of latex-based adhesives and paints can be enhanced by the addition of colloidal silica.

Silicon wafers cut from silicon single crystals must be polished to an almost atomically smooth surface before being used as substrates for electronic chips [302, 303]. Colloidal silica is the main component of the final polishing compounds for these materials. They act both as a fine, uniform abrasive and as a scavenger for reaction products of polishing additives that chemically attack the silicon.

Colloidal silicas have been used to bond and improve the attrition resistance of catalyst powders used in streams of reacting gas or liquid. The silica provides sufficient strength and hardness to prevent the catalyst pellets from being broken down and swept away by the stream. Acrylonitrile is made from propylene and ammonia by such a fluidized bed reaction [304, 305]. Ammonia-stabilized colloidal silicas are generally used in these applications because of the poisoning effect of sodium.

Photographic films and papers often incorporate colloidal silicas as grain growth regulators or dye receptors.

Beverages, such as wine, beer, or fruit juices can be clarified using colloidal silica as an aid to the flocculation of the proteins which cause the materials to be hazy.

4.8. Storage, Handling, and Transportation

Colloidal silicas generally undergo irreversible precipitation of the silica if frozen. Therefore, they are generally stored in heated buildings. If outdoor bulk storage is required, tanks should be heated and insulated in climates where freezing might occur. Heated trucks are typically used in cold climates for shipping colloidal silicas.

Colloidal silica is sometimes freeze-stabilized by addition of organic substances such as glycols. The amount added is insufficient to prevent freezing, but does prevent irreversible precipitation.

Storage in plastic, fiberglass-reinforced plastic, stainless steel or lined steel tanks is usually recommended.

Typically, the main hazard associated with colloidal silicas is their alkalinity. However, since the pH of most commercially available materials is < 10.5 they may irritate the skin or eyes, but do not cause irreversible burns. In applications where a respirable mist can be formed, operators should be protected by engineering design or suitable respirators. Since colloidal silica is amorphous, it is less toxic than crystalline silica.

4.9. Economic Aspects

Major manufacturers of colloidal silica and their trade names are as follows:

Bayer	Baykisol	(Germany)
Du Pont	Ludox	(United States)
Eka Nobel	Bindzil, Nyacol	(Sweden)
Hispano Química	Hispacil	(Spain)
Monsanto	Syton	(United Kingdom)
Nalco Chemical	Nalcoag	(United States)
Nippon Shokubai	Seahostar	(Japan)
Nissan	Snowtex	(Japan)

Estimates of the colloidal silica market discussed in this section are based on [238, 239].

The U.S. market for colloidal silica is the largest in the world. The total market for North America is estimated at > 14 000 t (100 % silica basis) and valued at $ 50×10^6 [236]. These figures include ca. 1500 t consumed in Canada. Kline estimates that the total West European market for colloidal silica was 5500 t (100 % silica basis) in 1992, valued at over € 15×10^6 [239]. In Japan colloidal silica production in 1988 was estimated at 4500 t (100 % silica basis) and was expected to grow significantly [238].

The total annual capacity for the manufacture of colloidal silica in North America is estimated at 16 000–21 000 t (100 % silica basis). The total capacity in Europe is estimated at 6000 t.

Nalco is the largest producer for the North American market followed by Du Pont and PQ Corporation. Eka Nobel of Sweden has a relatively small plant in the United States (Pro-Comp Inc.). Alchem, a joint venture of C-I-L Inc. and Nalco in Ontario, is the sole Canadian producer.

In the United States, Monsanto imports colloidal silica from its plant in Wales and small amounts are also imported from Japan. Exports from the United States are believed to be relatively small at about 1800 t/a. Nalco and Du Pont are the main exporters, and Japan, Taiwan, and Canada are the principal destinations. Some colloidal silica is also exported to Europe.

The largest producers of colloidal silica in Western Europe are Bayer in Germany, Eka Nobel in Sweden, and Monsanto in the United Kingdom, followed by Akzo in the Netherlands and Hispano Química in Spain. There are a few smaller producers in Italy and France.

Western Europe imports some colloidal silica from the United States and exports relatively small amounts to the United States, Eastern Europe, the Far East, and the CIS.

In 1987–1988 the North American market for colloidal silica was expected to grow at an average rate of 5 %/a, and the Western European market at 3.5 %/a in volume. The author estimates that the actual growth for both markets has been lower due to the world economic situation.

Colloidal silica prices vary with grade, silica concentration, volume purchased, and country in which it is sold. In the United States the price is about $ 1.80–1.95 per pound for electronic-grade material, and $ 1.15–1. 40 per pound for other grades (100 % silica basis). In Western Europe the prices vary in the range 5.5–8.3 DM/kg (100 % silica basis).

5. Silica Gel

5.1. Introduction

Silica gel [*63231-67-4*] (revised 1990 SiO_2: [*112926-00-8*]) has the nominal chemical formula $SiO_2 \cdot x\,H_2O$ and is a solid, amorphous form of hydrous silicon dioxide distinguished by its microporosity and hydroxylated surface. The structure of silica gel is an interconnected random array of ultimate polymerized silicate particles, called micelles, which are spheroidal and 2–10 nm in diameter (resulting in high surface areas of ca. 300–1000 $m^2/g\ SiO_2$). The properties of silica gel are a result of the silica micelles, their state of aggregation, and the chemistry of the micelle surface.

Control of the surface area, porosity, and surface chemistry of silica gel has led to numerous and diverse uses. Examples include adsorbents for water or other species, abrasives and thickeners in dentifrice, efficient matting agents in coatings, chromatographic media, and catalyst supports. The utility is reflected in an estimated world consumption of > 110 000 t/a, not including China, the CIS, and Eastern Europe.

The development of silica-gel science and technology began with the pioneering work of Graham reported in 1861 [306], although observations of gelation had been reported earlier [307, 308]. Commercial production began at the Silica Gel Corporation (now part of W. R. Grace & Co.-Conn.) with the process invented by Patrick in 1919 [309]. Commercial development and applications expanded worldwide [307], and the colloid chemistry of silica was explored further [310]. With the application of

NMR spectroscopy, small-angle X-ray scattering, and fractal geometry [311], further fundamentals of silica gel chemistry are being elucidated.

5.2. Structure, Properties, and Characterization

Structure. Silica gel is prepared by the neutralization of aqueous alkali metal silicate with acid [307, 309, 310]; for example:

$$Na_2O{\cdot}3.3\,SiO_2 + H_2SO_4 \rightarrow Na_2SO_4 + 3.3\,SiO_2\downarrow + H_2O$$

A complete synthesis of silica gel by this typical commercial route is outlined in Figure 32. Alternatively, stable silica sols may also be gelled [310]. Another method involves the hydrolysis of silicon alkoxides with water, catalyzed by acid or base [311].

The neutralization of sodium silicate initiates a polymerization of silicate tetrahedra in a random, amorphous manner to form small spheroids called micelles. The solution containing the micelles while still liquid is known as a hydrosol.

Gel formation occurs when the interaction of separate micelles through hydrogen bonding and eventual interparticle condensation becomes significant. The rate of gelation depends on many variables such as SiO_2 concentration, pH, temperature, and mixing; this is discussed in detail in [310, 311]. Polymerization and cross-linking continue after the hydrosol has solidified into a hydrogel. The random, amorphous structure is reflected in a lower skeletal density for silica gel of 2.1–2.2 g/cm^3 compared to quartz (2.65 g/cm^3) and the lack of X-ray crystallinity. The micelle, which is the ultimate particle, consists of SiO_2 in its interior and Si−OH on its surface. Solid-state ^{29}Si NMR indicates tetrahedral geometry about the silicon atoms and confirms the presence of bulk SiO_2 and surface Si−OH [312]. The micelle's size determines the specific surface area of the silica gel; a typical micelle size of ca. 2.5 nm in diameter corresponds to ca. 1000 m^2/g.

Once the gel network forms, several processing steps are performed to give the finished gel [313]. First, washing is normally performed to

Figure 32. Schematic of silica gel manufacture

remove dissolved salts. Because silica gel has a very low ion-exchange capacity for cations or anions at moderate pH, salt removal is a diffusion-controlled dilution process. Next, if desired, the interaction between micelles and micelle growth can be accelerated by aging in aqueous media under conditions where silica is slightly soluble. A process in which silica dissolves from regions of positive curvature and redeposits at regions of negative curvature reinforces the hydrogel network. Thus, a continuous gel structure is formed.

During the drying process, the surface tension of the solvent in the pores can act to shrink the hydrogel volume. In slow drying, as water is evaporated from a silica hydrogel, the structure collapses gradually due to the surface tension of water. Eventually a point is reached where even though water is still evaporating the gel structure no longer shrinks. At this point the gel is called a xerogel. Fast drying can minimize the shrinkage, and removal of water by solvent exchange followed by drying has the same effect. Materials that are dried with negligible loss of pore volume are known as aerogels. Solvent exchange with a water-miscible liquid such as ethanol to remove water from the hydrogel preserves pore volume after drying. Single or multiple solvent exchanges to lower surface tension results in less pore collapse during drying.

Drying of silica gels can also be carried out under conditions where the solvent in the pores is above its critical point and is vented while maintaining temperature and pressure. KISTLER [314] dried gels supercritically after replacing the water of the hydrogel with alcohol. Alternatively the liquid in the pores can be exchanged for liquid CO_2, which has more convenient critical-point properties [315, 316]. Considerable interest has been focused on such techniques due to the high porosity and mechanical properties achievable [311, 315, 317].

The resulting products from a scheme as in Figure 32 are high purity silica gels with controlled porosity. Transmission electron micrographs showing the pore structure of a silica gel are shown in Figure 33. Typical properties are as follows:

Chemical analysis (dry basis)	
SiO_2	99.71 wt %
Al_2O_3	0.10 wt %
TiO_2	0.09 wt %
Fe_2O_3	0.03 wt %
Trace oxides	0.07 t %
Physical analysis	
Total volatiles	5–6.5 wt %
Surface area	750–800 m^2/g
Pore volume	0.43 cm^3/g
Average pore diameter	2.2 nm
Apparent bulk density	0.72 g/cm^3
Skeletal density	2.19 g/cm^3
Specific heat	920 J kg^{-1} K^{-1}
Thermal conductivity	522 J m^{-1} h^{-1} K^{-1}
Refractive index	1.45

Surface Chemistry and Stability. The physical microporosity of silica gel is an important property, as is the chemistry of its bulk and surface species (Fig. 34). Pure silica gel has a hydroxylated surface covered with silanol groups. These hydroxyl groups are neither very acidic

Figure 33. Transmission electron micrographs of a silica gel similar to the fast-dried, high pore volume silica gel in Table 15, showing the micelle structures (ca. 20 nm) and apparent pores also ca. 20 nm in diameter
A) magnified ×235 000; B) magnified ×688 000

Figure 34. Schematic representation of the dehydration of a silica gel surface

nor basic, with p$K_a \approx 6$ and an isoelectric point at ca. pH 2. The hydroxylated surface is hydrophilic and adsorbs moisture readily. This adsorbed moisture can be desorbed thermally at 100–200 °C leaving behind ≈5.5 OH/nm^2 (or ca. 5 wt % silanol groups on a 300 m^2/g silica). These silanols are more difficult to remove but this can be done thermally by condensation to form siloxanes and water. Temperatures near 600–800 °C are required to dehydroxylate to ca. 1 OH/nm^2. At this silanol concentration the surface is hydrophobic.

Characterization. Numerous methods have been developed to characterize the porosity, structure, and chemistry of silica gels [310] and new methods continue to be applied [311].

With regard to porosity, differently prepared silica gels can be described on the basis of pore diameter d as microporous ($d < 2$ nm), mesoporous ($d \approx 2$–50 nm), or macroporous ($d > 50$ nm) [318]. The most generally useful methods for characterizing these structures with respect to surface area, pore volume, and pore-size distribution are nitrogen adsorption/desorption techniques. The primary method for surface area is the BET procedure [319] (ASTM D 3663–84 or DIN 66 131). Methods have been proposed to improve on the BET technique in small pores, such as the t-plot method [320], and the α_s method [321]. The related N_2 pore volume and pore-size distribution (pore volume as a function of pore diameter) methods are ASTM procedures D 4222–83 and D 4642–87, respectively. The porosity of a silica gel, determined by N_2 porosimetry, is shown in Figure 35. Alternative porosity measurement techniques include mercury porosimetry, water pore volume, and oil absorption.

Figure 35. Nitrogen pore-size distribution of a silica gel similar to the fast dried sample of Table 15
V = pore volume

Elemental analysis of silica gel focuses on trace elements in the range of < 1 wt %. Inductively coupled plasma atomic emission spectroscopy (ICP-ES) is becoming the preferred technique. pH measurement is performed on slurries and reflects the balance of residual trace elements (ASTM D 1208, DIN ISO 787 1X, JIS K 5101/24).

The moisture content of silica gel is important to provide an anhydrous basis for chemical analysis and because the hydration of the surface and pores (Fig. 34) is important to performance in applications. Most standards require two measurements: moisture loss on drying for 2 h at 105 °C (ASTM D 280, DIN ISO 787/II, or JIS K 5101/21) and loss on ignition after this drying by heating for 2 h at 1000 °C (ASTM D 1208, DIN 55 921, or JIS 5101/23). Another method often used in the United States prior to analysis to provide a solids basis is to measure total volatiles as a weight per cent loss on heating for 1 h at 954 °C.

The surface hydroxyl groups of silica gel can be characterized by thermogravimetric analysis [310], vibrational spectroscopy [311, 322], and nuclear magnetic resonance [311, 312, 323]. The information obtained concerns hydroxyl concentration, hydrogen bond interaction between hydroxyl groups, and distribution of $\equiv$Si$-$OH and =Si$-(OH)_2$ species on the surface. The adsorptive properties of variously hydroxylated silica materials are an indirect means of characterizing the surface.

Particle-size measurement is also important in silica-gel characterization (DIN 53 206). The method for granular gel is standardized sieve screening (ASTM D 4513). For particle sizes of roughly 1 to 1000 µm, static light scattering (ASTM) and conductivity methods are preferred for particle size analysis. For particle sizes of roughly 10 to 1000 nm, dynamic light scattering [352], electron microscopy, and small-angle X-ray scattering are used.

5.3. Production

Processes. The original production process of Patrick [309] as practiced by the Silica Gel Corporation starting in 1919 contains the main elements of modern processes using aqueous silicate raw materials. The initial step is the batch neutralization of sodium silicate (1.185 g SiO_2/cm^3) at 35–80 °C with 10 % HCl to form a hydrosol. A hydrogel then forms after 3–5 h at ambient temperature and is sized, washed with water to remove salts, and dried first at 75 –120 °C then 300–400 °C. A typical small pore gel made by this process is described in Table 15.

The Patrick gelation conditions, with relatively minor variation, have been the basis of most silica gel manufacture since. The next major change in silica gel products was the development of gels of higher pore volume and pore diameter by washing and aging hydrogels under basic conditions. Early references [324, 325] refer to this technology but large scale commercial introduction occurred around 1945. Base washing was a common industrial practice before 1950. In one example [326] a 17 % SiO_2 hydrosol gelled in about one hour. The hydrogel was broken up and washed with an aqueous ammonia solution of pH 9 for ca. 45 h then tray dried. Similar conditions are described for intermediate-density gel [313]. Alternative washing schemes are numerous and affect rates and equipment design or cost [353, 354]. In one such method that provides for faster throughput of silica hydrogel through the wash stages [354], the hydrogel particles containing reaction product salts are small (50–200 µm) and washing occurs via a hydrocyclone. In this case, the dried product typically has a surface area of 500 m^2/g and a nitrogen pore volume of 0.25 cm^3/g. A further variation involves fast drying [327] which increases the pore volume and diameter of such gels. Typical properties of acid-washed regular density, ammonia-washed intermediate density, and a flash-dried product are shown in Table 15.

Several methods of forming hydrogel, typically into spherical shapes, have been developed. Some methods employ a rapid gelation after mixing in a nozzle followed by spray setting [328 – 331], while others form beads in an oil phase immiscible with the hydrosol [332]. In some bead processes, recycled, dried, and powdered gel is mixed with the fresh sol to improve the physical integrity of the dried gels toward disintegration after contact with liquid water [333]. The direct formation of 5–10 µm gel particles by emulsion polymerization or particle-forming techniques is also possible. A process for the direct formation of 1–5 µm particles with

[c] >90 wt % water adsorption at 100 % R.H.

"double structure", i.e., with a core of dense silica and a shell of bulky amorphous silica, has been disclosed [334].

The supercritical preparation of aerogels has undergone a renaissance since earlier commercial production [335] because of renewed interest in the insulation and light-transmittance properties of these materials. The shift in applications toward large panels has created the need for what are described as aerogel monoliths [311]. One such process [315] forms a silica alcogel then exchanges the alcohol for liquid CO_2 before supercritical drying. The resulting monoliths show good light-transmittance properties. The monoliths, typically 500 × 500 × 2.5 cm, can be used to fill the space in the middle of double-pane windows. Another process involves reacting silanol groups on the internal pore surface with a reagent such as trimethylchlorosilane, which then minimizes shrinkage of the gel under drying conditions [355]. Dried gels of very high porosity and low density are thus obtained.

Environmental Protection. In the sodium silicate/H_2SO_4 processes the main environmental concerns are the fate of byproduct process chemicals, normally aqueous Na_2SO_4 and small amounts of aqueous NH_3, and pH control of this stream.

Quality Specifications. Typical quality criteria for silica gel are chemical purity, moisture content, and porosity. These properties depend on manufacturing conditions such as concentrations, gelling and washing times, pH, and drying conditions. Typical properties of silica gels are reported in Table 15. Application-specific properties are often measured for certain end uses (see Section 5.4).

Silica gel has been described by numerous organizations for the purpose of defining the quality necessary for use in food, cosmetic, and pharmaceutical applications. In the United States, monographs for silica gel are included in the Food Chemicals Codex (1981) and The United States Pharmacopeia–The National Formulary (1990). In Japan it is described in the Japanese Pharmacopeia, Standard for Cosmetic Materials, and JIS Z 0701. It is also on the "Positive" list for use in food-grade polyolefins. The EC is compiling permitted silica gel uses into a complete listing for member states. Until that listing is complete member states will maintain individual regulations.

5.4. Uses

Silica gel is used extensively in a wide variety of applications; here, some major uses are described.

Desiccants. The earliest well identified use for silica was as an adsorbent for water. The affinity of silica gel for water is affected by its state of activation (or moisture loading) and the degree of saturation of the surrounding fluid by water vapor. A plot of the affinity of silica gel for water vapor as a function of equilibrium relative humidity at ambient temperature is shown in Figure 36. The properties of two silica desiccants have been described in Table 15.

Figure 36. Water adsorption isotherms at room temperature as a function of relative humidity for several materials
a) Granular Al_2O_3; b) Zeolite A (Na^+ form); c) Regular density silica gel; d) Spherical Al_2O_3; e) Intermediate density silica gel

Silica gel is widely used in the narrow pore form to keep enclosed spaces dry, such as in cable junctions, pharmaceutical containers, and consumer goods. Silica gel is also used for drying natural gas. The wider pore form of silica is used to prevent local condensation in high-moisture environments and to absorb condensed mists of moisture. Another application is to use silica gel to maintain a constant humidity environment around art objects [336].

Desiccants have been described in several countries by standards Mil-D-3716B (United States), DEF STAN 80–22 (United Kingdom), and JIS Z 0701–77. These descriptions include standard properties and methods of analysis.

Adsorbents. Silica gel can adsorb many species other than water, particularly polar substances [337]. In addition to chemical processing, silicas have many uses in food processing. Treatment of beer with hydrogels, hydrous gels, or xerogels to remove haze-forming proteins is one example [325, 338]. Another food use is the adsorptive purification of glyceride oils [339]. Silica gels also are used extensively in chromatography [340].

Dentifrice. Silica gels have long been components of dentifrice formulations [341] but more recently were employed more for their suitable abrasiveness for cleaning than simply as carriers or thickeners. Xerogels [342] and hydrous gels [343] are used, but must compete with precipitated silicas [344] in this application. The abrasiveness of a dentifrice can be measured [345] and generally correlates with how effectively it cleans the teeth.

Coatings. Fine sized silicas (2–15 μm) are used extensively to control the reflectance of coatings [326, 327, 335]. By interrupting the surface of the coating the gloss of the surface (as measured by ASTM D 523) is reduced but particles too large can harm the appearance of the surface. The fineness of grind (ASTM D 1210–79) can be measured and specified. In clear coatings, the refractive index of the silica is important to maintain clarity. A typical matting agent has a particle size of ca. 10 μm, a pore volume of ca. 1.8 cm^3/g, and a fineness of grind on the Hegman scale of > 4 (ASTM test). A relatively new application for silica gels is in paper coatings for digital imaging, particularly by ink-jet printers [356]. In this application, the silica-rich coating serves to absorb ink-liquids and to control image appearance.

Microelectronics. The application of silica gels as insulators with low dielectric constants in microelectronics is developing. This use takes advantage of the air-containing pore structure to reduce the dielectric constant [357].

Catalysts and Catalyst Carriers. The high surface area of silica gel makes it an attractive solid on which to effect catalysis. Silica itself does not catalyze many reactions of commercial significance. Silica aluminas have acidic catalytic properties best exemplified in catalytic cracking [307, 346]. Silica gel is also used as a support in olefin polymerization [347 – 349].

Suppliers. Silica gel suppliers (with trade names following in parentheses) are summarized: Akzo, Asahi, BASF (Silica-Perlen, Silica-Pulver), Crosfield Chemicals (Gasil, Lucilite), Eagle, Fuji Silysia (Sylopute, Art Sorb), W. R. Grace & Co.-Conn. (Syloid, Sylobloc, TriSyl), Kali Chemie (KC-Trockenperlen), Millenium (Silcron), Mizusawa, PQ (Britesorb), Qingdao Hyiang, and Uetikon (Diamantgel).

5.5. Economic Aspects

Between 30–50 % of silica gel is estimated to be used in desiccant applications. Estimated production of silica gel in 1994 was > 110 000 t.

5.6. Legal Aspects

Toxicology and Occupational Health (see also Chap. 9). Silica gel is listed under TSCA in the United States, the Domestic Substances List (DSL) in Canada, the European Inventory of Existing Commercial Substances (EIECS), the Australian Inventory of Chemical Substances, and the Japanese Core Inventory (MITI) [358].

Silica gel is generally classified as synthetic amorphous silica. Epidemiological studies have indicated low potential for adverse health effects in humans [350]. Silica gel is not listed on IARC, National Toxicology Program (NTP), or OSHA carcinogen lists.

The IARC evaluation of amorphous silica is that there is inadequate evidence for carcinogenicity to humans or experimental animals. The phrase "inadequate evidence" indicated that the studies cannot be interpreted as showing either the presence or absence of a carcinogenic effect. For synthetic amorphous silica, there is no evidence of carcinogenicity to animals or humans [359].

A study found that amorphous silica particles are regarded as rather innocuous, not causing chronic adverse pulmonary effects [359]. In contrast, exposure to crystalline silica particles can cause both acute and chronic pulmonary inflammatory responses. The objective of this study was to evaluate mechanisms of pulmonary responses to amorphous and crystalline SiO_2 after subchronic inhalation. The study compared the pulmonary response of rats inhaling amorphous silica for three months at concentrations which resulted in a similar acute inflammatory response for both compounds at the end of exposure. The conclusion is that the persistence of crystalline SiO_2 appears to be most important for its long-term effects and that amorphous silica shows significant in vivo solubility. A further conclusion is that acute inflammatory parameters cannot be used as predictors for long-term outcome and that type II cell activation appears to be associated with fibrotic lesions. The study suggests that persistence of high level of cell replication and inflammation may be mechanistically involved in the development of neoplasia.

Cellular changes identified as neoplasms in this study were seen for rats exposed to crystalline silica and were not seen in the rats exposed to amorphous silica. Also, any pathology seen in animals exposed to high doses of amorphous silica was reversible, whereas the pathology for animals exposed to crystalline silica continued to the development of neoplasia [360].

Tests conducted for United States FDA approval for use in foods (see 21 CFR 160.105, 160.815, and 172.480) showed:

LD_{50} (mouse) 8000 mg/kg (limit of test)
LD_{50} (rat) 4500 mg/kg (limit of test)
6-month feeding tests (rat) at levels up to 10 % of diet produced no effects.

A long-term bioassay of chronic toxicity on mice and rats concluded that "proper dietary administration of micronized silica has proven to be generally safe with no long-term toxic effects" [351].

Storage and Transportation. Silica gel should be stored in sealed containers to protect product quality, particularly to avoid moisture adsorption or desorption. Silica gel is not considered a hazardous material by the International Air Transportation Association (IATA Resolution 618, Attachment "A", 1992), the U.S. DOT (49 CFR), or in EEC Council Directive 67/548/EEC.

6. Pyrogenic Silica

The term pyrogenic silica refers to highly dispersed silicas formed from the gas phase at high temperature. Nowadays, the most important production process is flame hydrolysis. The electric-arc process is of little and the plasma process of no economic significance. The designation pyrogenic used in this chapter therefore always refers to silica produced by flame hydrolysis.

6.1. Flame Hydrolysis

The flame hydrolysis process was developed in the late 1930s and patented in 1942 [361]. The

Figure 37. General process scheme of flame hydrolysis
a) Vaporizer; b) Mixing chamber; c) Burner; d) Cooling section; e) Separation; f) Deacidification; g) Hopper

original aim was to develop a "white carbon" as a reinforcing filler for rubber. However, for technical and economic reasons precipitated silicas (see Chapter 7) were adopted for this use.

In the meantime pyrogenic silica [*112945-52-5*] has found applications in numerous branches of industry.

Capacities for pyrogenic silicas amounted to ca. 100 000 t worldwide in 1991. Producers are Degussa (Aerosil), Cabot (Cab-o-sil), Wacker (HDK), and Tokuyama Soda (Reolosil).

6.1.1. Production Process

Silicon tetrachloride is the usual raw material for flame hydrolysis. It is continually vaporized, mixed with dry air and then with hydrogen, fed to a burner, and hydrolyzed:

$$2\,H_2 + O_2 \rightarrow 2\,H_2O$$

$$SiCl_4 + 2\,H_2O \rightarrow SiO_2 + 4\,HCl$$

The gases leaving the reaction chamber contain all of the silica in the form of an aerosol.

The silica is separated almost quantitatively from the hydrochloric acid- containing off-gas by cyclones (centrifugal separators) or filters. Treatment with steam and air in a fluidized-bed reactor is then carried out to remove residual hydrochloric acid adsorbed on the large surface of the silica. The hydrogen chloride is washed from the off-gases in adsorption columns to give hydrochloric acid in commercial concentrations. The hydrochloric acid formed can be reused by reacting it with silicon to produce silicon tetrachloride and hydrogen.

The properties of pyrogenic silica can be controlled by varying reaction parameters such as flame composition and flame temperature. Thus, desired specific surface areas in the range 50 to 400 m^2/g can be produced selectively.

The product, with a bulk density < 20 g/L, is pneumatically transported to packing machines, where the tapped density is increased to 50 –120 g/L by compacting rollers or vacuum packers.

A schematic of the flame hydrolysis process is shown in Figure 37.

It is also possible to use methyltrichlorosilane alone or mixed with silicon tetrachloride as raw material. In this case, however, simultaneous hydrolysis and oxidation is required, which requires modification of the production process.

6.1.2. Morphology

Flame hydrolysis produces extremely fine, mostly spherical particles with diameters of ca. 10 nm. The size of the average primary particles, which can be measured by transmission electron microscopy (TEM), ranges from 7 to 40 nm. The particle-size distribution becomes narrower with decreasing primary particle size (see Fig. 38).

The small particles give rise to high specific surface areas of ca. 50–400 m^2/g. This consists almost entirely of outer surface, which is not formed by pores, and is readily accessible to diffusion processes. The specific surface areas determined by adsorption (e.g., by the BET method

[362]), are in agreement with those determined by TEM within certain limits. Figure 39 shows the BET surface area as a function of the mean particle size measured by TEM.

Figure 38. Primary particle-size distribution of pyrogenic silicas with various specific surface areas
a) 300 m^2/g; b) 200 m^2/g; c) 90 m^2/g; d) 50 m^2/g

The primary particles do not occur in isolation, but form aggregates by intergrowth, and agglomerates through cohesion forces. In contrast to precipitated silicas, pyrogenic silicas cannot be produced in the form of defined aggregates or agglomerates. The primary particles can be identified by TEM, but it is not possible to distinguish aggregates from agglomerates [363].

Figure 39. Correlation of the average primary particle size with the specific surface area of different pyrogenic silicas

The size of the agglomerates actually present in a liquid or powder mixture depends mainly on the dispersion and mixing intensity during preparation.

Figure 40 shows a TEM photograph of a pyrogenic silica with an average primary particle size of ca. 40 nm and a specific surface area of

Figure 40. TEM photograph of a pyrogenic silica with an average primary particle size of ca. 40 nm and a specific surface area of ca. 50 m^2/g

Figure 41. TEM photograph of a pyrogenic silica with an average primary particle size of ca. 7 nm and a specific surface area of ca. 300 m^2/g

ca. 50 m^2/g, while Figure 41 shows one with an average primary particle size of ca. 7 nm and a specific surface area of ca. 300 m^2/g.

6.1.3. Solid-State Properties

Pyrogenic silicas are X-ray amorphous. For example, X-ray diffraction photographs with a detection limit of 0.2 % for Aerosil 200, a hydrophilic pyrogenic silica with a specific surface area of ca. 200 m^2/g, show no crystallinity [364]. This fact is of considerable significance for industrial hygiene, since current experiences indicate that the development of silicosis on inhalation of silica dust is associated with the crystallinity.

The refractive index of 1.45 is similar to that of silica glass. The particle size and the surface chemistry have a small but measurable influence on the refractive index. Transparent mixtures can be prepared from pyrogenic silicas and most organic polymers.

Pure pyrogenic silicas are thermally quite stable. Thus, heating for 7 d at 1000 °C results in no change of the morphology and no crystallization. The thermal stability is, however, significantly lower if other substances are present. Traces of alkali or alkaline-earth metal ions in particular act as mineralizers [365].

Since pyrogenic silicas are produced from readily vaporizable starting materials that can be easily purified by distillation, impurity concentrations resulting from the raw materials are very low. Generally, the silicon dioxide content is > 99.8 % after ignition for 2 h at 1000 °C to remove chemically and physically adsorbed water. The content of hydrochloric acid byproduct can be reduced to less than 250 ppm by suitable measures, which is adequate for most applications.

The purity of pyrogenic silicas is specified particularly for their use in pharmacy. The most important monographs concerning this are:

1) European Pharmacopeia 2 (Silica Colloidalis Anhydrica)
2) DAB 10 (Hochdisperses Siliciumdioxid)
3) U.S.P./National Formulary XVII (Colloidal Silicon Dioxide)

Pyrogenic silicas are largely inert chemically. They dissolve in strong alkali solutions with silicate formation and in hydrofluoric acid with the formation of silicon tetrafluoride. The solubility in pure water is similar to that of quartz (ca. 150

mg/L). Figure 42 shows the solubility behavior of a pyrogenic silica with a specific surface area of 200 m^2/g in the alkaline pH range.

Figure 42. Time dependence of the solubility of a pyrogenic silica in caustic soda

6.1.4. Surface Chemistry

Siloxane and silanol groups occur on the surface of the silica particles. The former are hydrophobic while the latter are hydrophilic and make the pyrogenic silica wettable. The silanol groups can occur isolated, bridged, or geminal (Fig. 43).

Figure 43. Siloxane and silanol groups on the silica surface

The silanol groups can be determined quantitatively by reaction with lithium aluminum hydride and measurement of the amount of hydrogen formed. The densities lie between 2.5 and 3.5 SiOH/nm^2 [366, 367]. The silanol groups are weakly acidic, which causes a zeta potential for the pyrogenic silicas of zero at a pH value of approximately two [368]. Pyrogenic silicas become preferably negatively charged by friction [369].

IR spectroscopy is important for the analysis of the surface chemistry of pyrogenic silicas [367, 370 – 373], and methods such as solid-state NMR spectroscopy promise further results. The following IR bands are of significance:

– O–D	2760 cm^{-1}
– C–H	2900–3000 cm^{-1}
–SiOH isolated	3750 cm^{-1}
–SiOH bridged	3000–3800 cm^{-1}
–SiOH combination band	4550 cm^{-1}
H_2O adsorbed	5200 cm^{-1}

Immediately after production pyrogenic silicas show mainly isolated silanol groups. In the course of time, adsorbed water reacts with strained siloxane groups and forms bridged silanol groups. This aging can easily be followed by IR spectroscopy (Fig. 44) [367].

Figure 44. IR spectra of pyrogenic silica (200 m^2/g specific surface area) shortly after production (A) and after storage for one year (B)

The desorption energies of both the chemically and physically bound water can be determined by gravimetric adsorption and temperature-programmed desorption [374]. Thus, the following energies were determined: 50 kJ/mol, for water hydrogen bonded to a silanol group, and 84 kJ/mol for water bonded to two neighboring silanol groups. The elimination of water from neighboring silanol groups and isolated silanol groups requires 122 kJ/mol and 130 kJ/mol, respectively.

The silanol groups undergo acid-specific reactions; examples include:

1) With hydride ions (e.g., $LiAlH_4$) [366]

$$=Si-OH+H^- \rightarrow =Si-O^- + H_2$$

2) Deuterium exchange [367]

$$=Si-OH+D_2O \rightarrow =Si-OD+HDO$$

3) Neutralization [375]

$$=Si-OH+NaOH \rightarrow =Si-ONa+H_2O$$

4) Chlorination [376]

$$=Si-OH+SOCl_2 \rightarrow =Si-Cl+SO_2+HCl$$

5) Esterification with diazomethane [376]

$$=Si-OH+CH_2N_2 \rightarrow =Si-O-CH_3+N_2$$

Summaries of the surface chemistry of finely divided silicas are given in [377, 378].

6.1.5. Surface Modification with Silicon Compounds

Pyrogenic silicas are hydrophilic; however, a hydrophobic character is more favorable for some applications. This requirement can be met by reaction with dimethyldichlorosilane [379, 380]. The resulting silica thus is no longer wettable by water and was introduced on the market in 1962 under the name Aerosil R 972. Apart from chloroalkylsilanes, mainly hexamethyldisilazane, alkoxyalkylsilanes, and polydimethylsiloxanes are used.

Apart from methyl and longer chain alkyl groups, organofunctional groups can also be anchored on the surface of pyrogenic silicas by using silanes. This form of modification was first used on a large scale for applications in dental materials. A pyrogenic silica with a low specific surface area is treated with γ-methylacryloxypropyltrimethoxysilane to give an active filler that can be chemically bonded to the polymethylmethacrylate matrix and provides the dental material with very good mechanical properties [381 – 383].

Another use of pyrogenic silicas modified with organofunctional silanes is in toners. Until recently photocopiers generally fixed the latent electrostatic image on a positively charged selenium layer. An electrostatically negatively chargeable toner is required for development, which contains a hydrophobic pyrogenic silica to improve the flow behavior and chargeability. In more modern copier systems the latent image is formed on an organic semiconductor layer, which is negatively charged and requires a positively chargeable toner. However, pyrogenic silicas tend to become negatively charged due to the presence of silanol groups even in hydrophobized products. Hence, a surface modification is necessary to allow positive charging. This can be achieved by using aminofunctional silanes, which undergo hydrolysis-stable anchoring to the silica surface [384 – 386].

6.1.6. Characterization

Pyrogenic silicas can be characterized well on the basis of chemical and physicochemical data; however, these do not allow a definite assessment of their suitability for a particular use, which requires application testing. The following test methods have proved useful to test the suitability for many uses and also for the quality control of hydrophilic, pyrogenic silicas:

1) BET surface area, m^2/g (DIN 66 131)
2) Drying loss, % (2 h at 105 °C; DIN ISO 787/II)
3) pH value (4 % aqueous suspension; DIN ISO 787/IX)
4) Silicon dioxide content, % (fuming with hydrofluoric acid, relative to the substance heated at 1000 °C for 2 h)

For hydrophobic or surface-modified pyrogenic silicas it is advisable to determine the carbon content instead of the silicon content, since the former provides information on the extent of surface loading.

6.1.7. Uses

Reinforcing Fillers. Pyrogenic silica is used in large quantities as an active filler in silicone rubber (→ Silicones). In RTV silicone sealants, both hydrophilic and hydrophobic pyrogenic silica are used (ca. 10 %) to modify mechanical properties such as Shore hardness, tensile strength, and tear strength. High temperature vulcanizing (HTV) silicone rubber requires ca. 30 % pyrogenic silica to improve the mechanical properties. Hydrophobic pyrogenic silicas with strongly reduced thickening action are used in liquid silicone rubbers. Theories of the reinforcing action of pyrogenic silica in silicone rubber are discussed in [387 – 389].

The tensile strength of vulcanized silicones with various silica fillers is shown in Figure 45.

Figure 45. Tensile strength of silicone vulcanizates containing a precipitated silica (FK 160), two hydrophilic (Aerosil 200/300), and two hydrophobic (Aerosil R 974/R 812) pyrogenic silicas

Pyrogenic silicas are also used as active fillers in natural and synthetic rubber, particularly if extremely high mechanical properties are required, as in cable sheathing, seals, or conveyor belts.

In fluoroelastomers, both hydrophilic and hydrophobic silicas improve the mechanical properties [390, 391], even under the action of aggressive gases.

Thickening and Thixotropization. An important application for pyrogenic silicas is the adjustment of the rheological properties of liquid systems such as paints, thermosetting resins, and printing inks. The increase in viscosity generally plays a minor role; thixotropization and the development of a yield value are decisive in practice. These effects are generally attributed to the formation of a three-dimensional network of silica agglomerates, which fixes the liquid in "cells" and thus increases the viscosity. The silica particles interact via silanol groups. The spatial network is destroyed by mechanical stress (e.g., stirring or shaking) to an extent which depends on the intensity and duration of energy input, whereby the viscosity decreases. The silica network regenerates when the stress is removed, and the original viscosity returns. This theory has proved suitable for simple, nonpolar liquids, but is not applicable to complex and/or polar systems, in which adsorption and solvation effects determine the rheological activity [392], especially in the case of hydrophobic pyrogenic silicas.

Hydrophilic pyrogenic silicas show the best thickening action in nonpolar liquids (Fig. 46).

Figure 46. Thickening effect of a pyrogenic silica with 200 m^2/g specific surface area (Aerosil 200) in various solvents a) Xylene; b) Butylacetate; c) Diacetone alcohol; d) Butanol

Antisettling Agents. Closely linked with the control of the rheological properties of liquid systems is the action of pyrogenic silicas as antisettling agents. The establishment of a flow limit hinders settling of suspended particles, depending on their density, size, and shape. If settling does occur, pyrogenic silica generally prevents caking of the sediment and ensures easy dispersibility.

This effect is mainly utilized in filler- or pigment-containing paints and plastics. Not only suspensions of lighter solids can be stabilized, such as silica-based matting agents, but also heavy anticorrosion pigments such as zinc dust or micaceous iron oxide. Both hydrophilic

and hydrophobic pyrogenic silicas can be used as antisettling agents. The most suitable type must be determined for each individual case, whereby additional effects, such as the water repellency of hydrophobic products in corrosion protection systems, must also be taken into consideration [393, 394].

Dispersants. In solid-containing liquid systems, pyrogenic silicas reduce the reagglomeration of the solid particles during the dispersion process, whereby a more favorable state of distribution is achieved. This effect is particularly important in pigment-containing systems, where both the gloss and also the tinting strength, and in the case of carbon black pigments also the jetness, can be improved by adding small quantities of pyrogenic silica [393].

Free Flow Agents. Some powders exhibit poor fluidity or they agglomerate on storage, particularly under the influence of pressure or moisture. The causes of agglomeration include solid bridges, which form by drying or pressure sintering processes, liquid bridges, electrostatic charging, and van der Waals forces [395, 396]. This can make use of the material difficult or even impossible. In many cases this can be remedied by the addition of hydrophilic or hydrophobic silicas. The reasons for this are complex. Thus, the small silica particles can envelop the powder particles and act as "ball bearings", hydrophilic pyrogenic silica can adsorb moisture and "render it harmless", or hydrophobic pyrogenic silica can slow down the absorption of moisture. The significantly smaller silica agglomerates can decrease the van der Waals forces between two powder particles by acting as spacers [396, 397]. Pyrogenic silica is used in fire extinguisher powders, tablet mixtures, toners, powder coatings, and table salt.

Other uses of pyrogenic silica include:

1) Adsorbents
2) Antiblocking agents for plastic films
3) Coatings
4) Catalyst supports
5) Matting agents
6) Grinding agents
7) Polishing agents
8) Raw materials for silica glasses
9) Thermal insulation
10) Additive carriers

6.1.8. Industrial Hygiene and Safety

Pyrogenic silica does not cause silicosis on inhalation (see also Chap. 9). So far no indication for this illness has been found for those employed in production who undergo regular medical tests [398]. However, since it can lead to irritation of the respiratory tract due to the fine particles, a MAK of 4 mg/m^3 total dust in inhaled air was applicable in 1991. This MAK value is not exceeded if suitable precautions are taken, e.g., lowest possible dust development upon handling or extraction of air (ventilation). Otherwise dust masks should be used. According to the findings so far pyrogenic silica is basically harmless by oral intake [399, 400]. Pyrogenic silica can cause a feeling of dryness on the skin, which can be easily remedied by washing and creaming.

Pyrogenic silica is susceptible to electrostatic charging on handling. If it is likely to come into contact with combustible gases or vapors, it is necessary to take the corresponding safety measures, such as careful earthing and utilization of explosion-proof plants.

6.2. Electric-Arc Process

The reduction of quartz sand with coal in an electric-arc furnace gives gaseous silicon monoxide, which is oxidized to finely divided amorphous silica by atmospheric oxygen [401]:

$$SiO_2 + C \rightarrow SiO + CO$$

$$SiO + CO + O_2 \rightarrow SiO_2 + CO_2$$

In a variant of this process the thickening effect of the electric-arc silica is increased by adding steam during oxidation followed by thermal treatment [402].

The matting agent TK 900 [*112926-00-8*] used in paints is a silica produced by Degussa using this process.

6.3. Plasma Process

Finely divided amorphous silicas can be produced in plasma burners. In one case quartz sand

is reduced to silicon monoxide with methanol at ca. 2000 °C. Subsequently, reduction with steam is carried out [403]. At present such silicas are not available commercially. A schematic of the plasma process can be found in [404].

7. Precipitated Silicas

7.1. Introduction

Precipitated silicas, like pyrogenic silicas and silica gels, are a synthetic, finely divided, white, amorphous form of silicon dioxide. Precipitated silicas have only been produced commercially since the 1940s. In the meantime, they have become the most important group of silica products on the basis of the amounts produced. Worldwide production capacity in 1999 was ca. 1 100 000 t, compared to ca. 400 000 t in 1970. Capacities in Europe, America, and Asia amount to 400 000, 340 000, and 360 000 t, respectively.

The largest producers worldwide are Degussa-Hüls, Rhodia, Akzo, and Crosfield in Europe, as well as PPG and Huber in the United States. The Asian market is additionally supplied by numerous local producers. Among these, the companies with the largest capacities are Nippon Silica and Tokuyama Soda in Japan, and Sam Yung and Kofran in Korea.

7.2. Production

Raw materials for the production of precipitated silicas are aqueous alkali metal silicate solutions (e.g., water glass) and acids, generally sulfuric acid [405 – 420]. Precipitation with hydrochloric acid [421, 422], organohalosilanes [423, 424], carbon dioxide [425, 426], or a combination of the latter with mineral acids [427] are of minor economic importance.

In the reaction of alkali metal silicate solution with mineral acid, the silica precipitates according to the following equation:

$$Na_2O{\cdot}3.3\,SiO_2 + H_2SO_4 \rightarrow 3.3\,SiO_2 + Na_2SO_4 + H_2O$$

In contrast to silica gels, which are produced under acidic conditions, in this case precipitation is carried out in neutral or alkaline media. The properties of the precipitated silicas can be influenced by the design of the plant equipment and by varying the process parameters.

The production process consists of the following steps: precipitation, filtration, drying, grinding, and, in some cases, compacting and granulation (Fig. 47).

Numerous possibilities exist for carrying out the precipitation [405 – 427]. So far only batch precipitation processes have attained economic importance, although continuous precipitations have also been reported [420]. Generally, acids and alkali metal silicate solution are fed simultaneously into water in a stirred vessel with the formation of silica seeds. In the course of the precipitation, three-dimensional silica networks are formed, accompanied by an increase in viscosity. The networks are reinforced by further precipitation of oligomeric silica and grow further into discrete particles with a decrease in viscosity. The formation of a coherent system and thus a gel state is avoided by stirring and increasing the temperature.

The properties of the silica can be influenced by varying important precipitation parameters such as pH, temperature, duration, and solid concentration. Additionally, the rate of addition of the acid and the intensity of stirring, which can be supplemented by a shearing action, also influence the properties of the silica.

The separation of the silica from the reaction mixture and the washing out of the salts contained in the precipitate is carried out in filter aggregates such as rotary filters, belt filters, or filter presses (chamber, frame, and membrane filter presses).

The solids content of the washed filter cake is 15–25 % depending on the type of silica and filter; therefore, drying requires the evaporation of large quantities of water. Depending on the desired properties of the end product, drying is carried out in spray, nozzle spray, plate, belt, or rotary dryers. Special product properties can be achieved by spray drying the filter cake after redispersion in water or acid [410, 413, 428].

To control the desired fineness of the particles, various mills and, if required, classifiers [429] are used. Special degrees of fineness can be achieved by air-jet or mechanical grinding [410, 430]. The silica is separated from the air in cyclones or filters.

Processes for the compression and granulation of precipitated silica have been developed [431, 432] to reduce the volume for transport and for certain uses and also to decrease the formation of dust on handling and processing.

Bags, big bags, containers, or transport silos are used for packaging and shipping. Information about the different methods of packaging and shipping is given in [433]; dust-free handling of precipitated silicas is described in [434]. In Germany the general dust limit of 4 mg total dust/m^3 air must be adhered to when handling precipitated silicas. Similar regulations apply in other countries.

7.3. Properties

7.3.1. Physicochemical Properties

Precipitated silicas consist mainly of spherical primary particles, generally intergrown in three-dimensional aggregates. These aggregates can pack together to form larger agglomerates. The terms primary particle, agglomerate, and aggregate are defined in DIN 53 206.

Some important physicochemical properties of several precipitated silicas are listed in Table 16.

The specific surface area is generally determined by the BET method (DIN 66 131; ISO 5794–1, Annex D), which measures both the outer surface and the surface of accessible pores. The specific surface area is of importance especially in reinforcement and adsorption applica-

tions. Precipitated silicas can be produced with specific surface areas of 25–800 m^2/g.

The mean particle size is important in the use of precipitated silicas as matting or antiblocking agents for paint systems and plastic films. The particle size can be determined by various methods either on the powder or after incorporation in a medium (e.g., water, paint, silicone rubber) [435].

The tamped density (ISO 787–11) is a measure of the weight of the powder and thus gives indications of the spatial requirement for transportation and a general guide for handling. The tamped densities of precipitated silicas lie in the range of 50–500 kg/m^3.

The loss on drying (ISO 787–2) includes the majority of the water physically bound to the silica and for precipitated silicas generally lies between 2.5 and 7 % (on leaving the supplier).

The loss on ignition (ISO 3262–11) includes the additionally chemically bound water (a siloxane group is formed from two neighboring silanol groups with the loss of a water molecule). Ignition losses for precipitated silicas generally lie between 3 and 7 %.

Generally the pH value (ISO 787–9) of precipitated silicas is ca. 7.

The dibutyl phthalate (DBP) absorption (ASTM D2414) is a measurement of the absorptive capacity and for precipitated silicas lies in the range of 175–320 g/100 g. The absorptive capacity is important for the conversion of liquids and pastes into powders.

The determination of the sieving residue (ISO 787–18) provides an indication of the amount of difficultly dispersible fractions in a precipitated silica.

7.3.2. Surface Chemistry and Surface Modification

Precipitated silicas have two different functional groups on their surfaces: silanol (Si−OH) groups and siloxane (Si−O−Si) groups.

These two groups substantially influence the surface properties and hence the application

Figure 49. Schematic of the reaction of the surface silanol groups of a precipitated silica with dimethyldichlorosilane

properties of precipitated silicas. The surface has 5–6 silanol groups per nm^2, which results in the hydrophilic character of precipitated silicas. Whereas the siloxane groups are generally chemically inert, the reactivity of the silanol groups allows chemical surface modification [436] of precipitated silicas. Thus, the reaction with organosilanes [437 – 439] or silicone fluids [440, 441] leads to hydrophobic precipitated silicas.

Hydrophobization is carried out industrially both by wet processes (e.g., addition of organochlorosilane to the precipitate suspension; see Fig. 49) and dry processes (e.g., the reaction of precipitated silicas with silicone fluids).

In coating processes, in contrast, no chemical reaction takes place; the coating agents are adsorbed on the silica surface. Wax coating with wax emulsions has become industrially important [410, 442, 443].

Surface modification is advantageous for certain applications (e.g., free flow agents, defoamers, and matting agents; see Section 7.4).

7.3.3. Chemical Composition and Analysis

The chemical composition of precipitated silicas (see Table 16) is generally less important than the physicochemical data with regard to the application properties. Furthermore, commercially available precipitated silicas differ only slightly in their composition.

The SiO_2 content is determined gravimetrically by fuming off with hydrofluoric acid (ISO 3262–17); the analysis of the metal-containing impurities is performed by atomic absorption spectrometry (AAS). The sulfate content is determined by complexometric titration (DIN 38 405/5), colorimetric titration (DIN 2462/8), or potentiometric titration.

The carbon content of modified silicas is determined by converting the carbon-containing component into CO_2 (ISO DIS 3262–19: 1994).

A survey of the chemical analysis of precipitated silicas is given in [444].

7.4. Uses

Precipitated silicas can be tailor-made to meet the requirements of various uses. Only the most important of the numerous applications (Fig. 50) are mentioned here.

Figure 50. Worldwide consumption and use of precipitated silica in 1999

The oldest and most important use of precipitated silicas is the reinforcement of elastomer products such as shoe soles, technical rubber articles, cable sheating, and tire compounds [445, 446].

The addition of 20–100 parts by weight of precipitated silica to 100 parts by weight of natural or synthetic *rubber* improves the tensile strength, hardness, tear strength, and abrasion resistance of the vulcanized material [447]. Furthermore, special precipitated silicas enable the

production of transparent vulcanized materials. The reinforcing effect of precipitated silicas is superior to that of natural or mineral fillers and, in contrast to carbon blacks, they allow the production of white and colored rubber articles.

In *cables*, they are used mainly in sheathing compounds for cables that are not fixed and must be differentiated from the background by a colored exterior (e.g., mining or excavator-hauling cables). The high resistance of the cable sheath to friction and tearing protects the inside of the cable from abrasion and damage.

Since the early 1990s precipitated silica has been used as a high-performance reinforcing filler in rubber compounds for *tires*. To take full benefit of silica in terms of tire performance, it is essential to use highly dispersible silica grades such as Ultrasil 7000 GR (Degussa-Hüls) or Zeosil 1165 MP (Rhodia) with a silane coupling agent. The use of highly dispersible silica in tread compounds leads to significant improvements in rolling resistance and wet traction of tires. Due to the possibility of achieving the best compromise of the three main tire-performance criteria ("magic triangle") – rolling resistance, wet traction, and tread wear – silica is now widely used in Europe, and demand in North America and Asia is growing significantly. The use of silica in the bodies of car and truck tires is becoming increasingly interesting owing to the need to further reduce rolling resistance to cut fuel consumption and CO_2 emissions [448 – 450].

Precipitated silicas are also used as reinforcing agents in *silicone rubber* [451, 452], where they replace the more expensive pyrogenic silicas in certain formulations.

In *thermoplastics*, precipitated silicas are used to improve specific properties. They act as antiblocking agents and are used to prevent plate-out effects in films and film production. They are also used to improve the mechanical properties of PVC flooring.

A further major application is the use as *carrier silicas* for liquids and semiliquids and as free flow agents for powder formulations, particularly of hygroscopic and caking substances. Of particular importance is high adsorptivity and good flowability of the silica. Such precipitated silicas absorb liquids or solutions to give powder concentrates that contain up to 70 % of the liquid [453]. In this way liquid materials are converted into a dry, free-flowing form, which can be mixed in any ratio with other dry substances. This is of particular importance in the animal-feed industry for the mixing of feed additives [454]. Materials converted into powder form include: choline chloride, ethoxyquin, molasses, and vitamin E acetate [455]. Fats can be converted into free-flowing powders for use as milk-substitute feeds [453, 455], mainly for the fattening of calves (Fig. 51). The same effects are utilized in the food industry, where products such as coffee whiteners (nondairy creamers) and mixed spices are produced and kept intact with the aid of the specific properties of synthetic silicas [462, 463]. Precipitated silicas are used as carriers for crop protection agents and insecticides [456, 464, 465].

Figure 51. Milk substitutes
Left: without addition; right: after addition of 1.5 % Sipernat 22 S

Precipitated silicas are being used increasingly in *toothpastes* as cleaning agents, since they clean effectively with a minimum of scratching [457]. Additionally, they control the rheological properties of toothpastes and also enable the production of transparent gels [458].

Figure 52. Reflection of light from shiny (left) and matted surfaces (right)

The surfaces of objects are matted for reasons of fashion but also to increase safety by avoiding dazzle. Special silica *matting agents* have been developed for matting of paints and varnishes [410, 429, 443]. The matting effect is the result of roughening of the surface on the microscopic scale, whereby the light is diffused and no longer directionally reflected (Fig. 52).

In the *paper industry* precipitated silicas are used as advanced fillers in, for example, newsprint to improve adsorptivity for printing ink. Strike through is reduced, and the coefficient of friction is adjusted. Silicas are used in special coated papers for ink-jet and direct thermal printing to enhance ink absorption [466].

Hydrophobic precipitated silicas are used increasingly in mineral-oil and silicone-oil *antifoam agents* to increase the antifoaming effect. They are used as foam regulators in laundry detergents [459] and in the production of paints and paper.

Further uses for precipitated silicas include the purification and stabilization of beer [460], and the analysis of blood [461].

Trade Names. Trade names for precipitated silicas include Sipernat, Ultrasil, Sident, Acematt (Degussa-Hüls); Hi-Sil, Flo-Gard, Lo-Vel (PPG); Tixosil, Zeosil (Rhodia); Zeodent, Hübersil (Hüber); Ketjensil, Perkasil (AKZO); Nipsil (Nippon Silica); and Neosyl (Crosfield).

7.5. Industrial Hygiene and Safety

Precipitated amorphous silica is nontoxic in rats after oral intake [462 – 464]. Neither eye irritation nor skin irritation is observed [465, 466]. Dryness of the skin after skin contact can be alleviated by washing and creaming. Inhalation of precipitated amorphous silica does not result in silicosis [467]. In addition, several epidemiological studies show no indication of silicosis in exposed employees [468 – 471].

When working with precipitated amorphous silica, the MAK value (4 mg/m^3 total dust) must be observed [472]. When appropriate precautions such as lowest possible dust development during handling and ventilation are taken, this value is not exceeded. Otherwise, dust masks should be worn.

8. Porosils

8.1. Introduction

Porosils are crystalline porous silicas of the general composition $SiO_2 \cdot M$, where M is an organic or inorganic guest molecule residing within the pores of the silica host framework. R. M. Barrer coined the name porosils to differentiate between porous aluminosilicate zeolites and a new class of compounds of distinct composition [473]. Due to their porous crystal structure porosils have properties similar to the zeolites; however, differences in chemical composition are responsible for their specific properties in catalysis, sorption, and molecular sieving.

Work in the field was initiated in 1978 by Flanigan et al. [474] who reported on the synthesis and crystal structure of the siliceous analogue of the commercially most important zeolite ZSM-5.

Figure 53. Skeletal projections of porosil framework structures
Si atoms are located in the nodes of the framework O atoms, which are close to the midpoint between 2 Si atoms, but are omitted for clarity
A) Projection of the AFI structure along the channel axis. The channel pore opening is confined by 12 Si atoms (12 MR); B) Projection of the FER, TON, MTT, MEL, and MFI structures along the straight channel axis. The channel pore opening is confined by 10 Si atoms (10 MR); C) Projection of the dodecasil layer. Pentagonal dodecahedra are arranged in layers which are the basic structural feature of DOH, MTN, DDR, and decadodecasil 3 H; D) Compilation of types of cage as found in clathrasil structure types ($[5^{12}]$ represents pentagonal dodecahedron, i.e., 12 five-membered rings)

The guest species M can be expelled by thermal treatment to give the pure silica form of the porosil. Therefore, porosils are considered to be the porous polymorphs of the structure family SiO_2. Up to now, 34 porosil structure types have been made, either by template-directed synthesis or post-synthesis treatment of aluminosilicate zeolites (Table 17) [475, 476]. In the synthesis of porosils the guest species M act as templates for the pores, defining their size and geometry [477]. During the post-synthesis treatment framework aluminum is substituted by silicon, and M is atmospheric gases or sorbate molecules [478].

Porosils are subdivided into zeosils and clathrasils according to the pore structure of the silica framework. Zeosils have channel-type pores with pore openings larger than 0.4 nm (Fig. 53). The channels may intersect to give a two- or three-dimensional pore system (see Table 17). Clathrasils have cage-type voids with pore openings much smaller than the free diameter of the cage and less then 0.45 nm (Fig. 53).

With the exception of melanophlogite, a rare mineral formed by low-temperature, low-pres-

* Dealuminated zeolites.
** Pore dimensionality and pore size (n-membered ring of SiO_4 units).

sure metamorphosis in, e.g., serpentine veins [479], all porosil structure types are synthetic materials. The ever increasing number of new porosil structure types reflects the efforts in the systematic investigation of the mechanism of formation of zeolites, for which porosils represent a simplified system. Besides porosils, water (clathrate hydrates), $AlPO_4$ (AlPO's), $GaPO_4$, and other III–V oxides (e.g., arsenates) also form neutral inorganic porous framework structures when synthesized in the presence of structure-directing guest molecules [475].

8.2. Physical and Chemical Properties

The physical and chemical properties of porosils are closely related to their crystal structure and composition. Porosils are colorless materials of hardness close to that of quartz. Since they are framework silicas, they exhibit no pronounced cleavage. Refractive indices vary systematically with the density of the silica framework (Fig. 54) [480]. This confirms that the nature of the Si−O bond accounts for most of the physical properties and is closely related to the natural

polymorphs of the SiO_2 structure family. The porosils are thermodynamically metastable and transform reconstructively to cristobalite at high temperature (e.g., melanophlogite: T > 950 °C [481]). Below 200 °C structural phase transitions to lower symmetry space groups have been reported for melanophlogite [482], dodecasil 3 C [483], decadodecasil 3 R [484], silica-ZSM-5 [485], and silica ZSM-11 [486].

Figure 54. Density of the silica framework of porosils and dense silicas versus refractive indices

For dodecasil 3 C, three consecutive phase transitions have been reported, with transformation from cubic to tetragonal, orthorhombic, and finally monoclinic symmetry [487]. This reflects the flexibility of the silica framework. Several phase transitions are ferroic (e.g., ferroelastic) indicating interesting physical properties for the material.

A number of porosils in the high-symmetry form exhibit negative volume expansion coefficients β. For example, silica-ZSM-5 contracts in the temperature range 393–975 K with $\beta = -15.1 \times 10^{-6}\ K^{-1}$ [488].

Since the composition of the host framework is SiO_2, porosils are electroneutral. The pores, therefore, contain only electroneutral guest species (i.e., ion pairs, molecules, and/or atoms). In contrast to aluminosilicate zeolites, porosils are hydrophobic [474, 489], preferentially sorbing aprotic organic molecules. The weak Lewis acidity of the electroneutral SiO_2 framework of the porosils reduces considerably their potential as materials for heterogeneous acid catalysis, for which the isostructural aluminosilicate zeolites are widely used [490]. The pore geometry of the porosil structure types varies from zero-dimensional pores (i.e., cavities) to three-dimensional pore systems (i.e., intersecting channels) (see Table 17). The pore openings are confined by $[SiO_4]$ units arranged in a ring (Fig. 53) (e.g., ten-membered ring, 10 MR: 10 SiO_4 units per ring). In general the sorption properties of the materials are related to the largest pore opening of the structure, which provides for the release of guest molecules and the access of sorbates to the internal surface. In clathrasils the maximum pore opening (6–8 MR) is too small for the exchange of the occluded species. The template-free material can be obtained only by calcination at > 600 °C. For 6 MR as maximum pore opening only very small atoms or molecules such as H_2 or He could be sorbed onto the silica framework (Table 18). Zeosils with pore openings of 8–12 MR are calcined at lower temperatures and could be used for the selective sorption of, e.g., *n*-alkanes (8 MR materials) or *p*-substituted aromatic compounds (10 MR materials) (Table 18). Because of the uniform character of the pore opening and the possibility of tailoring the size of the pores, porosil- containing membranes, such as those already available for zeolites, could be useful for separation processes [491, 492].

Table 18. Idealized pore diameters and potential sorbates for various pore openings

Pore opening	Planar ring diameter, nm	Potential sorbates (diameter in nm)
6 MR	0.27	He (ca. 0.23) H_2 (ca. 0.23)
8 MR	0.44	alkane (ca. 0.43)
10 MR	0.60	aliphatic and aromatic six-membered rings (ca. 0.6)
12 MR	0.77	substituted ring systems

8.2.1. Zeosils

Physical and chemical properties specific to zeosils are related to their crystal structure. The channel-like pores allow access to the internal

surface of the material for sorbates that meet the geometrical requirement of the pore window.

The free diameter of the individual materials, however, varies considerably due to the flexibility of the silica framework. Idealized values for the pore openings are given in Table 18. Because of the hydrophobic properties of the silica framework and the geometry of the internal pore system, zeosils are of particular interest for various applications. In the presence of water zeosils sorb selectively hydrophobic organic molecules in the vapor and liquid phase [493]. Sorption of monomers into the silica framework followed by polymerization leads to one-, two- or three-dimensional polymeric filaments inside the zeosil framework, as already demonstrated for zeolites [494]. The deposition of semiconducting materials [495] and metal atom clusters [496] inside, e.g., the zeosil cavity of silica-A or silica-faujasite creates new materials with interesting properties due to the limited size of crystallites built within the pores. The sorption of polar organic molecules such as *p*-nitroaniline also leads to changes in symmetry and polarization of the host–guest composites, leading, e.g., to nonlinear optical properties [497]. For a review on new applications of zeosils, see [498].

8.2.2. Clathrasils

The clathrasil structure types have cagelike pores. Species inside the cavities are too large to pass through the 4 MR, 5 MR, 6 MR, or 8 MR windows without their decomposition. In general, clathrasils in the as-synthesized form have no exchange capacity or sorption properties. After calcination at high temperature (> 600 °C) the decomposition of the guest species may lead to a guest-free porosil with very narrow pores that is suitable for sieving and sorption processes (cf. Table 18). The properties of clathrasils are, therefore, linked to properties introduced by the guest molecules clathrated in the formation process. Because of the high thermal and chemical stability of the silica host framework, clathrasils have been proposed as containers for radioactive gases (e.g., krypton) [499]. The synthesis of the clathrasil dodecasil 3 C with a number of nonglobular guest molecules leads to a distortion of the cubic symmetry of the silica framework. At room temperature the materials have acentric symmetry and, therefore, nonlinear optical properties [500]. The temperature of the phase transition to the acentric space group depends on the nature and the concentration of the guest molecule in the silica framework and is in the range between slightly below room temperature and ca. 200 °C.

8.3. Manufacture of Porosils

With the exception of melanophlogite, all porosil structure types are synthetic materials made directly from an active form of SiO_2 or by dealumination of high-silica zeolites.

8.3.1. Synthesis of Porosils

Structure-directing templates play a key role in the synthesis of porous silicas [501, 502]. Since the templates are occluded within the pores during synthesis, it is their size and shape which determine the size and shape of the pores of the silica framework. Organic amines have proved to be the most efficient templates. Up to now ca. 100 different molecules have successfully been used for the synthesis of porosils [501, 503, 504]. Globular species such as xenon, quinuclidine, and 1-aminoadamantane preferentially stabilize the cage-like voids characteristic of clathrasils. Chain-like amines such as the α,ω-diamines of propane, butane, pentane, etc., stabilize channel-like voids. The size of the pore depends on the size of the template. Whereas pyrrolidine leads to preferential formation of dodecasil 3 C by occupying a 16-hedral cage, 1-aminoadamantane is occluded within a 20-hedral cage in dodecasil 1 H (Fig. 55). Zeosil structure types with 10 MR channels are formed in the presence of aliphatic chain-like templates (α, ω-diamino-*n*-alkanes); 12 MR channels are formed with molecules containing sequences of *p*-substituted heterocycles (e.g., 4,4′-trimethylenedipiperidine).

8.3.2. Dealumination of Aluminosilicate Zeolites

Porosils marked with an asterisk in Table 17 have been obtained exclusively by post-synthesis treatment of aluminosilicate zeolites. Aluminum

Figure 55. A) Van der Waals model of Xe as guest atom within the pentagonal dodecahedral cage; B) Van der Waals model of 1-aminoadamantane as guest molecule within the icosahedral cage

is selectively extracted from the silicate framework and replaced by silicon [505]. The dealumination procedure includes successive chemical and hydrothermal treatment of the material in order to extract and remove the framework aluminum atom. A typical procedure is the calcination of the synthesis product at 300–500 °C to expel the organic template, exchange of the cations with ammonium, and steaming at ca. 600 °C to remove the aluminum.

8.3.3. Formation of Melanophlogite

So far melanophlogite is the only known natural porosil. In synthesis experiments the conditions of formation have been simulated and are of low temperature (ca. 100–200 °C) and low (authogenic) pressure. The material has been described as a trace occurrence from five localities in very different geological settings. However, the nature of the porosil structure types and the wide range of structural features suggest that further natural variants may exist, especially in hydrothermally active areas (e.g., geysers).

9. Toxicology

The effect of the dust that arises when working with silica is of primary importance from a toxicological point of view, especially in the case of long-term exposure of several hours per day. This applies to naturally occurring and synthetic as well as to crystalline and amorphous. As far as industrial medicine is concerned, local contact with the skin and mucous membranes is important. In the case of inhalation of the dust, the effect on the respiratory tract is significant.

The effect of silica-containing dust on the respiratory tract depends on:

1) The physical and chemical properties (e.g., the particle size and the specific surface area)
2) The concentration administered
3) The daily and total duration of exposure

9.1. Experiences with Humans

After long-term exposure at work, the effects of crystalline or amorphous SiO_2 dust on the respiratory tract of humans are well known and have been widely reported (for reviews, see [506 – 509]).

Crystalline Silica Dust. The classification into common, accelerated, and acute forms of silicosis [506] is based on the time interval between the beginning of exposure to silica and the first appearance of silicotic changes that are detectable in a X-ray picture. A rapid manifestation and an accelerated course of the disease are caused primarily by long-term inhalation of higher concentrations of SiO_2 dust.

The common form of silicosis (simple silicosis) occurs roentgenologically after about twenty or more years of exposure. The content of

crystalline SiO_2 in the dust that causes silicosis in workers is often less than 30 % [506].

The accelerated form of silicosis (5–15 years) develops after a shorter exposure to higher concentrations of SiO_2 dust. Progressive massive fibrosis is often observed on the X-ray picture [506].

The acute form, also known as silicoproteinosis, develops in 1–3 years. The clinical symptoms include rapidly deteriorating function of the lungs, which is always fatal.

The progression of silicosis even after the termination of exposure is especially characteristic, and there is still no effective treatment.

For this reason, it is essential that the legal regulations for working with crystalline SiO_2 are obeyed [510 – 512].

Amorphous Silica Dust.

Amorphous Synthetic Silica. From experimental long-term inhalation tests on rats, it is known that high concentrations of some synthetic amorphous silicas can cause nodular (fibrotic) changes in the lungs of the animals during the exposure phase [513]. However, the regression of the nodules (fibrosis) in the lungs after the termination of the exposure phase is characteristic of the biological action of these amorphous silica dusts. In a treatment-free, follow-up observation phase of several months, a clear time-dependent regression of the changes in the lungs of the experimental animals could be detected after three, eight, and up to twelve months (see below) [513, 514]. In the case of the neighboring lymph nodes, the regression of the morphological changes observed within the inhalation phase was established histologically [513, 514].

In-depth investigations carried out by company doctors over periods of up to 12 years [515] and from 1 to 32 years [516] have confirmed that until now long-term contact with amorphous synthetic silicas has not resulted in a single case of silicosis.

Established MAK [511] and TLV regulations [512] must be complied with when working with amorphous synthetic silicas. If these fixed limiting values are exceeded – especially for a longer period of time – an overtaxing of the respiratory passages and a corresponding biological defense reaction in the bronchial tubes and, especially, in the lung tissue must be expected.

Vitums et al. observed that fibrosis of the lungs was caused by exposure to flue dust containing silica with a wide particle-size distribution, such that as produced in the manufacture of ferrosilicon or quartz glass [517].

Amorphous Natural Silicas. A distinction is made between exposure to amorphous synthetic silica dust and exposure to natural amorphous silica dust (diatomite). The latter can contain small amounts of crystalline SiO_2 and, according to some studies, can cause silicosis in humans on long-term exposure [507].

Carcinogenicity of Silica Dusts in Humans. In many cases, industrial workers exposed to crystalline silica dust exhibit a higher incidence of lung cancer. However, exposure to silica dust is often complicated by other hazards such as polycyclic aromatic hydrocarbons, asbestos, and smoking, which makes a causal analysis extremely difficult. According to Goldsmith et al. [518], at least two studies show a strong association between silicosis and lung cancer: the analysis of the Swedish pneumoconiosis register by Westerholm [519] and a similar study by Finkelstein [520] in Ontario, Canada. However, the same authors [518] also stated that a completely convincing causal relationship cannot be concluded. A possible association between silicosis and lung cancer is also discussed in [521], based on data from a clinical cancer monitoring register. A relationship between tumors of the upper intestinal tract and the ingestion of quartz particles in food in North China has been suggested [522]. A correlation was made between the incidence of cancer of the esophagus and the consumption of plant products that contain silica fragments and fibers for a region in North China, in northeast Iran, and in Transkei.

9.2. Animal Experiments

Long-Term Inhalation of Silica Dust. In specifically designed, practice-oriented long-term inhalation studies, various types of crystalline and amorphous silica dust have been thoroughly tested on rodents. Rats [513, 514, 523, 524] were mainly used, but rabbits [514, 525, 526] and guinea pigs [514] were also employed.

The elimination rate in rats has been determined in an inhalation experiment with highly

disperse *amorphous silica*. In the case of Aerosil 200, for example, after the termination of inhalation, 65–75 % of the dust was eliminated in one month, 80–90 % in two months, and 95 % in three to five months. It is possible that the rate of solubilization of these hydrophilic silicas also plays a role [513].

It was found in retention studies on rats [513] that in the case of longer term inhalation (28 times four hours in 36 days) of highly disperse *amorphous silica* dust, the continuous elimination during the exposure phase is very high. This means that the formation of large SiO_2 deposits in the lungs is improbable [513]. In contrast, in long-term inhalation experiments with *quartz* dust the tendency towards formation of deposits was higher [513].

After the termination of a long-term inhalation study on rats with Aerosil 200 (12 months, 4 per day; concentration: 45 mg/m^3), some of the animals were subjected to treatment-free observation for another 3 to 8 months and then killed [513]. Subsequently, a histological investigation and chemical analysis of SiO_2 in the lungs and lymph nodes were performed. In the follow-up observation period, it was found that the nodules in the lungs were reduced to small residual foci. The lymph nodes, which were still enlarged after three months, had greatly regressed after eight months. Similar observations have also been made in previous inhalation experiments with Aerosil.

In a long-term inhalation experiment on rats with *quartz* [524] (12 months, 5 per day, 5 per week; concentration:10 mg/m^3; standard quartz No. 12, Dörentrup quartz), some of the animals were subjected to treatment-free observation for another 4 weeks to 6 months after the termination of exposure and then killed. In this follow-up observation period, it was possible to detect silicotic reactions in the lungs and reticulohistiocytic cells typical of quartz in the lymph nodes. There was an increase in the silicotic nodules in the lungs after six months and fibrosis of the mediastinal lymph nodes had clearly increased.

Examination of lungs and accompanying lymph nodes of the individual groups of animals at various time intervals showed that in the case of *quartz*, a long residence time in the lungs must always be expected, but that deposits of finely divided *amorphous silica* are relatively quickly and extensively eliminated [513, 524]. This is true of amorphous silicas with a specific surface area of > 100 m^2/g [513].

Injection of Silica Dust. The tissue reaction typical of a particular silica dust can be determined in animal experiments by means of a single intratracheal or intraperitoneal injection.

The intratracheal injection of a high dose of *quartz* resulted in a massive local accumulation of dust [524]. The tissue reaction caused by an injection of this type is similar to the picture of acute silicosis. Fast reactions of this kind in the lung tissue – comparable with the exposure of workers to high concentrations of quartz [515] – can also be produced in animal experiments with very high inhalation concentrations (400 mg/m^3) [524].

The general effect of a particular dust (acute toxicity) and the local harmful (cytotoxic) effects are deduced from the tissue reaction observed in rats after intraperitoneal SiO_2 injections. Cytotoxicity can occur in the form of nodular fibrosis (dust nodules) or surface fibrosis that leads to extensive coalescence of the abdominal organs [513].

The reaction of lung tissue on longer term inhalation of SiO_2 dust cannot be directly inferred from the results of the intratracheal and intraperitoneal injections. Thus, the physiologically important reactions of the organism in the course of SiO_2 retention and SiO_2 elimination can be determined only in long-term inhalation tests with a sufficiently long, treatment-free, follow-up observation period.

The morphological changes in the lungs after long-term inhalation of *natural crystalline* SiO_2 progress after the termination of exposure, whereas with *synthetic amorphous silica* dust the morphological changes regress after the termination of exposure (reversibility).

Carcinogenicity of Silica Dusts in Animal Tests. Lymphomas have been found in rats after intrapleural, i.p., i.v., and direct application in the thymus gland of various silica modifications [527, 528]. The tumor incidence differed for various species of rat, and no tumors were observed in mice and hamsters. A synergistic effect has been reported for silica dust and benzo[*a*]pyrene [529], as has been found for other dusts (e.g., coal, TiO_2). This is presumably the result of chemicophysical surface ef-

fects, which may also be involved in tumor promotion. Tests have shown that Min-U-Sil causes tumors in rats in the intratracheal test [530]. Tissue scarring has been discussed as the cause. Min-U-Silis strongly fibrogenic and extremely finely divided.

1. Structural Chemistry of Silicates

More than 95 vol % of the earth's crust is composed of quartz and a few rock-forming silicates (plagioclase 42 vol %, potash feldspar 22 vol %, quartz 18 vol %, amphibole 5 vol %, other silicates 12 vol %). Silicon compounds are also present in the hydrosphere, mainly as dissolved silica. A large number of silicates have been identified in extraterrestrial material [1].

The widespread abundance of silicate minerals is accompanied by a diversity of practical uses (Table 1). Silicates are components of technical materials such as cement (→ Cement and Concrete) and glass (→ Glass, Glass Ceramics). Granite and sandstone are used as building materials. Quartz (→ Silica) is the raw material for producing waterglass, silicon (→ Silicon), and silicon compounds (→ Silicon Compounds, Inorganic, → Silicon Compounds,

Sillimanite	refractory masses	0.15
Andalusite	refractory masses	
Kyanite	refractory masses	
Mullite	refractory masses	0.005
Zircon	refractory material, ceramics, zirconium compounds	0.1
Spodumene, petalite	production of lithium	
Beryl	production of beryllium	
Chrysotil asbestos	(high toxicity)	4 (1978)

∗ Including nepheline, leucite: 4.5×10^6 t/a.

1.1. Structural Classification

Silicates comprise the largest, most extensive, and manifold class of minerals. One reason is that the bond energy of the Si – O bond is higher than that of the Si – Si and Si – H bonds (bond energies, kJ/mol: Si – O, 452; Si – Si, 222; Si – H, 318). Comparison with the values for carbon (C – O, 358; C – C, 346; C – H, 413) reveals why the skeletons in silicates are Si – O – Si – O chains instead of the C – C – C chains in carbon chemistry. The second reason is the ease with which silicon – oxygen tetrahedra can be linked to form rings, chains, layers, or three-dimensional frameworks. Diversity is increased by isomorphous substitution of silicon by small cations (mostly Al^{3+}, but also other tri- and divalent cations $B^{3+}, Fe^{3+}, Ga^{3+}, Be^{2+}, Zn^{2+}, Mg^{2+}$). In the 2 : 1 clay mineral sauconite $Zn_3[Si_{4-x}Zn_xO_{10}(OH)_2]$, Si^{4+} is substituted by Zn^{2+}. Synthetic mica phases in which Co^{3+} and Ni^{3+} replace Si^{4+} have been reported [1].

The common coordination number of silicon bonded to oxygen is four, but a few silicates together with the SiO_2 modification stishovite contain sixfold coordinated silicon, e.g., $Mg[SiO_3]$ (high-temperature modification), $(NH_4)_2[SiP_4O_{13}]$, $Ca_3[Si(OH)_6][SO_4][CO_3] \cdot 12\,H_2O$ (thaumasite), modifications of $Si[P_2O_7]$.

The most comprehensive classification of silicates is presented by Liebau [1–3] (Table 2). The term *multiplicity* (M) denotes the number of single polyhedra, rings, chains, or layers that are linked to the complex anion. *Dimensional-*

ity refers to the infinite extension of the anion: $D = 0$, groups; $D = 1$, chains; $D = 2$, layers; $D = 3$, framework. A silicate that contains double tetrahedra, as in $Sc_2[Si_2O_7]$ (thortveitite, Fig. 1B), is called a disilicate ($M = 2$, $D = 0$). Orthoenstatite $Mg_2[Si_2O_6]$ (Fig. 2A) is a monopolysilicate that contains single chains of silicon – oxygen tetrahedra.

Figure 2. Monopolysilicates
A) Zweier single chains (pyroxenes); B) Dreier single chains (wollastonite, $Ca_3[Si_3O_9]$

Sometimes, particularly in the technical literature, silicates of composition $MO \cdot 2\,SiO_2$, $MO \cdot 3\,SiO_2$ (M = metal) are called di- and trisilicates, respectively. This practice is in contradiction to IUPAC rules and must be abandoned. Also, the term "metasilicates" for silicates M_2SiO_3, $MSiO_3$, $M_2(SiO_3)_3$ should be abandoned because these silicates can be cyclo- or polysilicates.

Connectedness of $[SiO_4]$ tetrahedra is a further parameter that should be mentioned in classifying silicate structures. A $[SiO_4]$ tetrahedron can share common oxygen ions with 0, 1, 2, 3, or 4 $[SiO_4]$ tetrahedra; this is indicated by Q^0, Q^1, Q^2, Q^3, or Q^4, respectively. The connectedness of silicon – oxygen tetrahedra can be obtained from magic angle spinning – NMR (MAS – NMR) measurements. This is particularly advantageous in the study of amorphous materials or silicates with high levels of defects or of unknown structure.

Mineralogists classify the silicates into neso-, soro-, cyclo-, ino-, phyllo-, and tectosilicates (Table 3).

In classifying silicates on the basis of the way in which the silicon – oxygen tetrahedra are linked to each other, it should be remembered that the real structure is determined by the interaction between the $[SiO_4]$ tetrahedra and the nontetrahedral cations (Section 1.3).

1.2. Oligo- and Cyclosilicates

When not specified otherwise, references concerning structure, crystallographic data, or synthesis of the silicates mentioned are found in [1].

Single $[SiO_4]$ tetrahedra are found in *monosilicates* (Fig. 1A) such as forsterite $Mg_2[SiO_4]$, olivine $(Mg, Fe)_2[SiO_4]$, phenakite $Be_2[SiO_4]$, garnets $M^{12}_3M^6_2[SiO_4]_3$ ($M^{12} = Mg^{2+}$, Fe^{2+}, Mn^{2+}; $M^6 = Al^{3+}$, Fe^{3+}, Cr^{3+}), and zircon $Zr[SiO_4]$. Because of the high charge of the $[SiO_4]^{4-}$ anion, the stability of monosilicates increases in the order:

$$K_4[SiO_4] < Ca_2[SiO_4] < Ca_3Al_2[SiO_4]_3 < Zr[SiO_4]$$

Examples of *disilicates* (Fig. 1 B) are thortveitite and barysilite $MnPb_8[Si_2O_7]_3$. Synthetic $Ag_{10}[Si_4O_{13}]$ is a *tetrasilicate*. *Oligosilicates* with unbranched chains $M = 8$, 9, 10 have been synthesized.

A few *monocyclosilicates* (with single rings, $M = 1$) and a *dicyclosilicate* are shown in Figure 1 C – F.

Several mono- and cyclosilicates are of practical importance. Magnesium silicate, $Mg_2[SiO_4]$, is used as a refractory material (forsterite products, Section 2.4). Olivine (ca. 2.3×10^6 t/a) is mainly used as flux for slags in blast furnaces but small amounts are needed as foundry molding sands (Section 2.4). Garnets are utilized as bearings, polishing powder, abrasive products, and precious stones. (The garnets used as ferrimagnetic materials are yttrium and rare-earth iron garnets $M^{3+}_3Fe_5O_{12}$ which consist of $[FeO_4]$ tetrahedra in place of $[SiO_4]$ tetrahedra.) Thortveitite (with scandium ions partially substituted by yttrium ions) is an important scandium mineral.

Table 2. Classification of silicates [1]

Dimensionality		Multiplicity			
		1	2	3	4
0	Oligosilicates	monosilicates	disilicates	trisilicates	tetrasilicates
0	Cyclosilicates	monocyclosilicates	dicyclosilicates	tricyclosilicates	tetracyclosilicates
1	Polysilicates	monopolysilicates	dipolysilicates	tripolysilicates	tetrapolysilicates
2	Phyllosilicates	monophyllosilicates	diphyllosilicates	triphyllosilicates	tetraphyllosilicates
3	Tectosilicates	tectosilicates			

Table 3. Nomenclature of silicates used by mineralogists

Dimensionality	Multiplicity				
	1		2	3	4
0	nesosubsilicates	nesosilicates	sorosilicates		
0			cyclosilicates		
1			inosilicates		
2			phyllosilicates		
3	tectosilicates				

Several oligo- and cyclosilicates are valued as semiprecious or precious stones: garnets, olivine (chrysolite), zircon (hyacinth, jargon), beryl (emerald, aquamarine, heliodor, dioptas), turmaline (rubellite, schorl, indigolit).

Zircon is an abundant accessory mineral, for example in glass ceramics (→ Glass Ceramics). The radioactivity of rocks is often caused by the thorium and uranium content in zircon.

1.3. Polysilicates

Monopolysilicates. Polysilicates are abundant minerals, several are of practical importance. Single- chain polysilicates (dimensionality 1, multiplicity 1) are classified according to the number of silicon – oxygen tetrahedra contained in the repeat unit of the chain (*periodicity,* $P = 2$, 3, etc.). Figure 2 shows polysilicate single chains with periodicities of two and three. Monopolysilicates are known with periodicities in the range 3 – 24 ($P = 24$ in synthetic $Na_{24}Y_8[Si_{24}O_{72}]$ [1]).

The large group of pyroxenes (Fig. 2 A) consists of monopolysilicates with zweier single chains. Examples include enstatite ($Mg_2[Si_2O_6]$), diopside ($CaMg[Si_2O_6]$), and spodumene ($LiAl[Si_2O_6]$). Spodumene is a source for lithium (→ Lithium and Lithium Compounds, Chap. 3.1.1.) and glass ceramic production (→ Glass Ceramics). Enstatite and diopside are sometimes found in ceramic masses (→ Glass Ceramics). Several calcium silicates contain dreier single chains, for example wollastonite ($Ca_3[Si_3O_9]$, modifications 1T, 2M, 7T, Fig. 2 B). Wollastonite is used as a ceramic material, as a filler in plastics and paints, and as a substitute for asbestos.

Figure 3. Dipolysilicates
A) Einer double chain (high-temperature sillimanite, $Al^6[AlSiO_5]$ (hT)); B) Zweier double chain (amphiboles, e.g., tremolite, $Mg_5Ca_2[Si_4O_{11}]_2(OH)_2$); C) Dreier double chain (xonotlite, $Ca_6[Si_6O_{17}](OH)_2$; D) Dreier double chain (epididymite, $Na_2Be_2[Si_6O_{15}] \cdot H_2O$)

Dipolysilicates. The arrangement of the tetrahedra in sillimanite (high-temperature modification) is shown in Figure 3 A. However, the tetrahedral Al^{3+} and Si^{4+} ions are almost completely ordered so that sillimanite contains zweier double chains (Fig. 3 B) [1]. Zweier double chains are also the skeletons in am-

phiboles (Fig. 3 B). Xonotlite and epididymite are dipolysilicates with dreier double chains (Fig. 3 C, D).

Figure 4. Mutual adjustment of polysilicate anions and columns of $[MO_6]$ octahedra
A) Enstatite, $Mg_2[Si_2O_6]$; B) Wollastonite, $Ca_3[Si_3O_9]$ (low-temperature modification); C) Synthetic $Ba_2[Si_2O_6]$ (high-temperature modification) $Na_2Be_2[Si_6O_{15}] \cdot H_2O$)

Oligopolysilicates. Synthetic oligopolysilicates are $Ba_4[Si_6O_{16}]$ (zweier triple chain), $Ba_5[Si_8O_{21}]$ (zweier fourfold chain), and $Ba_6[Si_{10}O_{26}]$ (zweier fivefold chain).

Influence of Nontetrahedral Cations on the Structure of Polysilicates. The nontetrahedral cations exert a significant influence on the structure of polysilicates, in particular on their periodicity [4]. The mutual adaption of the conformation of the silicate chains to columns of $[MO_n]$ polyhedra is shown for enstatite, wollastonite, and synthetic $Ba_2[Si_2O_6]$ (high-temperature modification) in Figure 4. The dimensions of two $[MgO_6]$ octahedra (ionic radius of Mg^{2+}: 0.072 nm) in enstatite (Fig. 4 A) correspond to the repeat unit (identity period; two tetrahedra) of the stretched zweier single chain. In wollastonite (Fig. 4 B) the dreier single chain fits the column of the considerably larger $[CaO_6]$ octahedra (two octahedra and three tetrahedra; ionic radius of Ca^{2+}: 0.10 nm). A further increase of the ionic radius of the octahedral cation (Ba^{2+}: 0.135 nm) allows the adjustment of two $[SiO_4]$ tetrahedra to one $[BaO_6]$ octahedron: the polyanion assumes the form of a zweier single chain with the identity period distinctly smaller than in enstatite. Further examples of the adaptation of the silicate chain to edge-sharing $[MO_6]$ octahedra are shown for pyroxenes and pyroxenoids in Figure 5 [4].

Figure 5. Adjustment of polysilicate anions to "slabs" of $[MoO_6]$ octahedra
A) Ferrosilite-III, $FeSiO_3$ (high-temperature, medium-pressure modification) neuner single chain and $[FeO_6]$ octahedra; B) Pyroxmangite-type $MnSiO_3$ (medium-pressure modification) (pyroxmangite = $(Fe,Mn)_7[Si_7O_{21}]$), siebener single chain and $[MnO_6]$ octahedra; C) Rhodonite-type $MnSiO_3$ (low-pressure modification) (rhodonite = $(Mn, Ca_5)[Si_5O_{15}]$), single chain and $[MnO_6]$ octahedra

Other factors besides the size of the nontetrahedral cations (e.g., electronegativity and valency) also control the conformation of the polysilicate anion [2, 4].

1.4. Phyllosilicates

1.4.1. Monophyllosilicates

Layers of silicon – oxygen tetrahedra are formed when silicate single chains are linked with each other. A simple possibility is to build up the zweier single layer (Fig. 6) by connecting zweier single chains. The term *directedness* indicates the way in which the apical oxygen ions of the $[SiO_4]$ tetrahedra are oriented. In Figure 6 A all apical oxygen ions point in the same direction.

Figure 6. Formation of a zweier single-layer phyllosilicate by linking zweier single chains
A) Unfolded layer with terminal oxygen ions pointing in the same direction; B) Folded layer with terminal oxygen ions pointing up and down: $Li_2[Si_2O_5]$; C) Folded layer in petalite, $Li^{[4]}Al^{[4]}[Si_2O_5]_2$

In many other cases, however, they point in opposite directions (Fig. 6 B, C; Fig. 7).

Figure 7. Folding of tetrahedral layers in anhydrous monophyllosilicates
A) $Li_2[Si_2O]_5$; B) α-$Na_2[Si_2O_5]$; C) β-$Na_2[Si_2O_5]$; D) Sanbornite, $Ba[Si_2O_5]$ (low-temperature modification)

The layers shown in Figure 6 are highly flexible, even when the terminal oxygen ions alternate between both sides. The layers can be stabilized in three ways:

1) The layers are folded
2) The layers are linked to form diphyllosilicate anions or structures with higher multiplicities
3) The layers are linked to octahedral layers of nontetrahedral cations (Section 1.4.5)

Folded zweier single layers are found in several alkali and barium phyllosilicates (Fig. 7 A–D). The degree of folding depends on the cation. The layers are highly folded in $Li_2[Si_2O_5]$ (Fig. 7 A). The occurrence of different modifications of $Na_2[Si_2O_5]$ (Fig. 7 B, C) reveals that the convolution (degree of folding) is not only determined by the nontetrahedral cation.

A divalent cation must balance the charge of two $[SiO_4]$ tetrahedra. This increases the folding of the layer. The silicates $Ca[Si_2O_5]$ and $Sr[Si_2O_5]$ do not exist because the folding of the layers, which in turn is a consequence of the electrical field of the cations, provides coordination numbers too small for calcium and strontium ions. In the presence of barium ions (Fig. 7 D), which have a larger ionic radius, the degree of folding is not as large and provides sites for barium ions with sufficiently high coordination numbers (9 in sanbornite $Ba[Si_2O_5]$, low-temperature modification).

Anhydrous, single-layer silicates containing solely trivalent cations are not known because even strong convolution cannot produce a well-balanced charge distribution. However, Li^+ and Al^{3+} form a very stable, anhydrous, layer silicate with highly folded layers (petalite, $Li^{[4]}Al^{[4]}[Si_2O_5]_2$, Fig. 6 C). The stability is related to the tetrahedral coordination of Li^+ and Al^{3+} ions which is a consequence of the high degree of layer folding induced by the trivalent aluminum ion.

Examples of monophyllosilicates with layers composed of silicate chains with $P > 2$ are apophyllite (Fig. 8) and gillespite $BaFe[Si_4O_{10}]$ with vierer single layers. Synthetic $CaCu[Si_4O_{10}]$, isostructural to gillespite, was used as a blue pigment in wall paintings ("Egyptian Blue"). The mineral name is cuprorivaite.

Figure 8. Vierer single layer in apophyllite, $KCa_4[Si_4O_{10}]_2(F, OH) \cdot 8H_2O$

1.4.2. Diphyllosilicates

Stabilization of zweier single layers by linkage to diphyllosilicate anions is illustrated in hexacelsian, $Ba(AlSiO_4)_2$ (high-temperature modification, Fig. 9). Further examples are vierer double layers in naujakasite and reyerite and even neuner double layers in stilpnomelane.

Figure 9. Diphyllosilicates: zweier double layer in hexacelsian, $Ba[(Al, Si)O_4]_2$ high-temperature modification

1.4.3. Alkali Silicates

See also Chapter 3. Among the anhydrous alkali silicates only natrosilite, $Na_2[Si_2O_5]$, occurs as a mineral [5]; all others are synthetic.

$Na_4[Si_2O_6]$ is a monopolysilicate containing zweier single chains. Most of the alkali silicates are monophyllosilicates with zweier single layers: $Li_2[Si_2O_5]$ (Fig. 7 A); α-, β-$Na_2[Si_2O_5]$ (Fig. 7 B, C); $Na_4[Si_6O_{14}]$; $KH[Si_2O_5]$ [6]; and $K_2[Si_4O_9]$. Silicates with Si : O ratios $< 2 : 5$ contain Q^4 tetrahedra besides the Q^3 tetrahedra. Potassium analogues of $Na_2[Si_2O_5]$ are unknown [1].

Anhydrous alkali silicates are formed when quartz is melted with sodium or potassium carbonate or hydroxide (alkali silicates, waterglass). The reaction product is dissolved in water to form waterglass solutions. δ-$Na_2[Si_2O_5]$ is considered as a builder and possible substitute for zeolites in washing powders [7].

Several hydrated alkali silicates occur as minerals:

Kanemite	$NaH[Si_2O_5] \cdot 3H_2O$	[8]
Makatite	$Na_2[Si_4O_8](OH)_2 \cdot 4H_2O$	[9]
Magadiite	$Na_2[Si_{14}O_{29}] \cdot 11H_2O$ *	[10]
Kenyaite	$Na_2[Si_{20}O_{41}] \cdot xH_2O$ *	[10]
Revdite	$Na_2[Si_2O_5] \cdot 5H_2O$	[11]
Grumantite	$NaH[Si_2O_5] \cdot 0.9H_2O$	[12]
Silinaite	$NaLi[Si_2O_5] \cdot 2H_2O$	[13]

* MAS – NMR measurements reveal that the formula should be written as $Na_2H_2Si_{14}O_{30} \cdot xH_2O$, $Na_2H_2Si_{20}O_{42} \cdot xH_2O$ [14]. EUGSTER [10] reported the composition $Na_2Si_{22}O_{45} \cdot 10H_2O$ for kenyaite.

The structures of sodium monosilicates $Na_2H_2[SiO_4] \cdot xH_2O$ ($x = 1 - 8$) [15], makatite [16], and silinaite have been determined [13]. Makatite contains vierer single layers. The zweier single layer in silinaite shows a directedness not observed previously: the slightly kinked zweier single chains alternate such that in one chain the apices point up and in the adjoining chain the apices point down. The different dimensions of the $[LiO_4]$ tetrahedra and $[NaO_2(OH_2)_4]$ octahedra which hold the layers together, impose a slight wave in the silicate layer.

The natural alkali silicates and several other alkali silicates ($Na_2H_2Si_8O_{18} \cdot xH_2O$ [17]; $K_2H_2Si_{14}O_{30} \cdot xH_2O$; $K_2H_2Si_{20}O_{42} \cdot xH_2O$) can be easily synthesized from dispersions of SiO_2 in aqueous NaOH or KOH solutions [17–20]. A characteristic property of these sili-

Figure 10. Preparation of crystalline silicic acids from alkali phyllosilicates by exchanging protons for the interlayer cations

Figure 11. Clay mineral structure
A) Zweier single layer ("tetrahedral sheets"); B), C) Layers of edge-sharing $[MO_6]$ octahedra ("octahedral sheets")
Clay minerals with octahedral sheets as in (B) are called "trioctahedral", those with sheets (C) are called "dioctahedral".

cates is their cation exchange capacity (see Section 1.4.4). Possible practical uses include ion exchangers, adsorbents, or builders in detergents [21].

1.4.4. Crystalline Silicic Acids

Exchanging protons for the cations sandwiched between the silicate layers transforms the alkali phyllosilicates into crystalline acids (Fig. 10). In spite of the fact that the first crystalline silicic acid was prepared from α-$Na_2Si_2O_5$ in 1924 [22], most textbooks of inorganic chemistry refer to the orthosilicic acid $Si(OH)_4$ as the only oxo acid of silicon. The crystal structures of two $H_2Si_2O_5$ acids prepared from α-$Na_2Si_2O_5$ were determined by Liebau [23].

Presently, more than 15 crystalline acids are known and comprise at least six modifications of $H_2Si_2O_5$. The acids are derived from the natural and synthetic alkali silicates mentioned above, from several synthetic and natural cuprous silicates, and from a few other silicates such as apophyllite, carletonite, and gillespite [24–26]. The acids derived from

$Na_2H_2Si_{14}O_{30} \cdot xH_2O$, $K_2H_2Si_{14}O_{30} \cdot xH_2O$, and $K_2H_2Si_{20}O_{42} \cdot xH_2O$ have been considered for practical uses. These acids are interesting alternatives to various forms of silica. Practical applications may be related to adsorption properties [27] and the capability to intercalate neutral organic molecules (Section 1.4.6). A few acids even adsorb anionic surfactants (together with the gegen ions) in the interlayer space [28].

Figure 12. Linking of zweier single layers to octahedral sheets (dotted areas) in clay minerals
A) Kaolinite, $Al_2[Si_2O_5(OH)_4]$; B) Antigorite, idealized $Mg_3[Si_2O_5(OH)_4]$

1.4.5. Clay Minerals

See also Chapter 2.

In clay minerals (Table 4) zweier single layers (Fig. 11 A) are linked to octahedral sheets (Fig. 11 B, C). (In clay mineralogy the single tetrahedral and octahedral layers are called tetrahedral and octahedral sheets; the assembly of these sheets is called a layer [29].) The structures provide a good example of different types of directedness. The terms "clays, kaolins and bentonites" are used somewhat differently by geologists and in practical applications (see Chaps. 1, 5, 7 in [31]). A clear distinction must be made between "clay" (the rock) and "clay mineral" (the mineral) [32].

1:1 Clay Minerals. In kaolinite ($Al_2[Si_2O_5(OH)_4]$) all terminal oxygen ions of the zweier single layer (tetrahedral sheet) point to one side and simultaneously belong to the octahedral sheet (Figs. 11 A, 12 A,13 A). Thus, the octahedra around the octahedral cations consist of these oxygen ions and additional OH^- ions.

Figure 13. Linking of tetrahedral and octahedral sheets in clay minerals
A) 1 : 1 clay minerals (kaolinite, serpentines); B) 2 : 1 clay minerals (micas, vermiculites, smectites)

As the dimensions of the octahedral and the tetrahedral sheets do not match exactly ($b_{oct} \neq b_{tetr}$, Fig. 11), mechanical stress arises between both sheets (for details see [1, 29]). This causes curling of the crystals when their thickness decreases below a certain value [33]. Halloysite crystals are composed of kaolinite-type layers separated by a water layer, and often assume a tubular morphology.

The misfit between both types of sheets in the serpentine minerals (chrysotile, antigorite, lizardite), which are the trioctahedral counterparts of kaolinite (idealized formula $Mg_3[Si_2O_5(OH)_4]$), also leads to the curling of

Table 4. Classification of 1 : 1 and 2 : 1 clay minerals [30]

ξ [a]	Group	Octahedral character [b]	Predominant octahedral cation [c]	Species
Layer type 1: 1				
	kaolin – serpentine	tri	Mg^{2+}	lizardite, chrysotile [d], antigorite [d]

the chrysotile crystals. This results in the formation of tubes (tubular morphology of asbestos) or in the alternation of the terminal oxygen ions in a bandlike manner as in antigorite (Fig. 12 B).

The major mineral of this group is kaolinite, the most important mineral in kaolins. Total world production was ca. 25×10^6 t in 1992 (US Bureau of Mines, 1992) (→ Clays). It is used in the ceramic industry (ca. 20 %) and as a filler and coating pigment in paper production (ca. 50 %) [31, 34]. Kaolin is also needed for the production of zeolites (→ Zeolites) and ultramarines (→ Pigments, Inorganic, Chap. 3.5.).

2: 1 Clay Minerals. 2 : 1 clay minerals consist of two zweier single layers ("tetrahedral sheets") which enclose a central octahedral sheet (Fig. 13 B). The diversity of this group of phyllosilicates (Table 4) results from:

1) The occurrence of di- and trioctahedral layers (Fig. 11 B, C)
2) Isomorphous substitutions in the octahedral sheet
3) Isomorphous substitutions in the tetrahedral sheet, mainly Al^{3+} for Si^{4+}

In addition, cationic sites can be vacant, and protons may dissociate from OH^- ions or associate to them or to O^{2-} ions. Depending on the type and concentration of the substitutions and defects, the layers can assume negative charges. The number of charges per formula unit ($[(Si,Al)_4O_{10}]$ unit) is the most essential parameter used to characterize the 2 : 1 clay minerals.

The chemical composition of the 2 : 1 clay minerals is represented by:

$$\underbrace{M^{\nu+}{}_{\xi/\gamma}\,(H_2O)_n}_{\text{Interlayer space}}$$

$$\underbrace{\{(M^{3+}, M^{2+}, M^{+})^{(6-x)+}_{2-3}[Si_{4-y}Al_yO_{10}(OH)_2]\}^{\xi-}}_{\text{Layer}}$$

where ν is the valency of the interlayer cation and ξ is the layer charge.

The general formula indicates that the number of octahedral cations (M^{3+}, M^{2+}, M^{+}) varies between 2 and 3. Mostly, the occupancy is near 2 (dioctahedral minerals) or 3 (trioctahedral minerals). An extensive survey of chemical compositions is given in [31].

Figure 14. Structural relations between some silicates
A) Talc, $Mg_3[Si_2O_5]_2(OH)_2$; B) Palygorskite, idealized $Mg_5[Si_2O_5]_4(OH)_2(OH_2)_4 \cdot 4\,H_2O$, for exact formula see [29]; C) Sepiolite, idealized $Mg_4[Si_2O_5]_3(OH)_2 \cdot 4\,H_2O$, for exact formula see [29]

In Table 4, the clay minerals are classified according to their layer charge ξ and their di- or trioctahedral character. The silicates with uncharged layers are pyrophyllite (idealized $Al_2[Si_4O_{10}(OH)_2]$) and talc ($Mg_3[Si_4O_{10}(OH)_2]$). *Talc* (Fig. 14 A) is a raw material in the ceramic industry (→ Talc). It is used in the production of insulating materials (→ Insulation, Electric, Chap. 3.1.2.2.), as a filler (paper, paints, cosmetics, elastomers, thermoplastics), and as a carrier material for pesticides. *Pyrophyllite* finds similar uses [31].

Montmorillonite is the most important smectitic mineral (Table 4) of the bentonite rocks (→ Clays). The various applications of bentonites (production ca. 8×10^6 t in 1992; US Bureau of Mines, 1992) are based on the special properties of montmorillonite, in particular its fine particle size ($< 2\,\mu m$), intracrystalline reactivity (swelling in water and organic liquids, ion-exchange properties, see Section 1.4.6), binding of organic materials and colloidal behavior [31]. Only a few of the many hundreds of applications (→ Clays, Chap. 5.2.) [31, 35] are mentioned here. The special rheological properties of bentonites are exploited in the application as a foundry sand binder, for oil well drilling, iron ore pelletizing, in the building industry (in particular for subterranean curtains), in geotechnics, and as sealing materials; for pelletizing animal feed, as fillers and adsorbents (e.g., in clarifying and decolorizing mineral, animal and vegetable oils, beer, and fruit juices) and as a carrier material for pesticides. The profitable use as pet litter should not be overlooked.

Synthetic smectites are hectorite-type materials which are produced more easily than montmorillonites under mild hydrothermal conditions. Hectorite is a very low-charged smectite ($\xi \approx 0.20 - 0.25$ eq/unit) that contains Li^+ ions in the octahedral sheet. It has similar uses to bentonite [36]. The synthetic materials are used in the pharmaceutical industry (e.g., as thickeners, thixotropic agents, gel-forming materials) and seem to provide suitable properties as components in muds for drilling very deep wells [31, 35].

The largest amounts of *vermiculite* (production about 0.65×10^6 t/a) are used in the form of light, expanded aggregates consisting of exfoliated crystals (see Section 2.9).

Illites are very fine, mica-type minerals, and essential components of soils.

Mica is used in the form of sheets, ground powders, or micronized and is described in detail elsewhere (→ Mica). Most synthetic products are fluorinated micas. Formation of fluorophlogopite in glass ceramics gives this mate-

rial a precision machinability with conventional metal-working tools (→ Glass Ceramics) [37].

Chlorites. Chlorites are composed of silicate layers (similar to the 2 : 1 clay minerals mentioned above) that are separated by metal hydroxide layers $M(OH)_2$ or $M(OH)_3$ [29]. Chlorites are not used on an industrial scale but are abundant in soils and are found in clays.

Mixed-Layer Minerals. Mixed-layer minerals are very abundant in common clays and soils. The crystals are composed of layers which either differ in the composition and layer charge or are of different structural types. In most cases, the sequence of the layers is random. Typical combinations are [31] illite – smectite, mica – vermiculite, mica – chlorite, smectite – chlorite, chlorite – vermiculite, and kaolinite – smectite.

Some mixed-layer minerals also have a regular sequence of layers [31]:

Rectorite = muscovite (or paragonite) – montmorillonite
Tosudite = dioctahedral chlorite – smectite
Corrensite = chlorite – vermiculite (or trioctahedral smectite)

Palygorskite and Sepiolite. Palygorskite (Fig. 14 B) and sepiolite (Fig. 14 C) provide further examples of phyllosilicates with single layers of different directedness. The two-dimensional octahedral sheet is split into one-dimensional bands comprising eight or five octahedra. In the tetrahedral sheet some of the tetrahedra are inverted. Bands of three zweier single chains with different directedness alternate in sepiolite whereas the bands in palygorskite are composed of two zweier single chains. Channels are therefore formed in the structure which contain water molecules and exchangeable cations. The cations are bound as a consequence of isomorphous substitutions in the tetrahedral and octahedral sheets. The minerals have zeolitic properties and show a certain cation-exchange capacity. Sepiolite crystallizes as fibers with diameters of 5 – 30 nm and a length of 10 nm – 4 µm. Fibers of palygorskite are 15 – 30 nm thick and 0.5 – 4.5 µm long.

Sepiolite and palygorskite are being increasingly used as thickeners, thixotropic agents, adsorbents, supports of pesticides and catalysts, and pet litter [31].

1.4.6. Intracrystalline Reactions

Kaolinite, 2 : 1 clay minerals, and alkali phyllosilicates are intracrystalline-reactive, layered materials [38]. The interlayer space is accessible to guest molecules or ions (Fig. 15).

Figure 15. Intracrystalline reactions of phyllosilicates
A) Phyllosilicates with uncharged layers (kaolinite, crystalline silicic acids); B) Phyllosilicates with charged layers (2 : 1 clay minerals, hydrated alkali silicates)

Kaolinite takes up various organic compounds (urea, hydrazine, dimethyl sulfoxide, short- chain acid amides, potassium and ammonium acetate) between the layers so that they are separated by a mono- or bilayer of neutral guest molecules (Fig. 15 A). In most cases, these molecules can be displaced by other molecules [31]. Intercalation of organic compounds promotes delamination of kaolinite particles and can improve the mechanical stability of porcelain. Kaolin modified by intercalation of urea was used in China (mainly in the Sung period, 960 – 1280) in the production of very thin porcelain (egg-shell porcelain) [39].

The most striking difference between the behavior of di- and trioctahedral minerals is that the

trioctahedral 1 : 1 clay minerals such as antigorite do not intercalate guest molecules. Pronounced intercalation capability is observed for the crystalline silicic acids [28,38].

Intracrystalline-reactive phyllosilicates with charged layers can undergo various reactions (Fig. 15 B) [31]. Most important for technical applications is the intracrystalline swelling of smectites by interlamellar adsorption of water. The layer separation of calcium smectites does not normally exceed 1 nm. In the presence of sodium ions, however, the layers separate completely and form colloidal dispersions [31]. This process and the related changes in flow behavior are of great importance in many practical applications (building industry, subterranean curtains, foundry sand binder, oil well drilling fluids etc. [31]).

A further essential reaction is the exchange of the interlayer cations [31]. Soda activation is an important technical process in which interlayer calcium ions are displaced by sodium ions. Fixation of potassium ions by more highly charged 2 : 1 clay minerals plays an important role in soils. Clay minerals are considered as useful adsorbents in environmental technology because of their ability to bind heavy metal ions by cation exchange [31,40,41]. Radioactive nuclides may be removed by clay adsorbents, for instance cesium ions by vermiculites and shales [42]. Even radioactive iodide ions can be adsorbed by modified clay minerals [43].

The third reaction of technical importance is the binding of organic cations. Organo-modified bentonites are used in many applications, mainly as adsorbents, thickeners, or thixotropic agents in organic systems (lubricants, greases, paints, or asphalt). In environmental technology, organic derivatives of clay minerals adsorb toxic substances [31,40,41,44].

1.5. Tectosilicates

Almost all tectosilicates (framework silicates) contain quaternary tetrahedra such that the ratio of tetrahedral cations to oxygen is 1 : 2. The fundamental chain periodicities are $P = 2$, 3, 4, 6: cristobalite, tridymite $P = 2$ (Fig. 16 A); quartz, keatite $P = 3$; zeolites: laumontite, gismondine, harmotone $P = 4$; chabazite, silicalite-1 $P = 6$. Nephelines, $(Na_{1-x}K_x)[AlSiO_4]$, have a tridymite structure (Section 2.2). The feldspars (Section 2.1) have loop-branched dreier frameworks (Fig. 16 B) based on a branched dreier single chain. The black tetrahedra in Figure 16 B form a dreier single chain and additional tetrahedra (stippled) bridge two tetrahedra of this chain [3]. Cordierite, $Mg_2[(Al_4Si_5)O_{18}]$, has an open-branched vierer framework.

Figure 16. Framework silicates
A) Zweier framework of tridymite $[SiO_2]$; B) Loop-branched dreier framework of feldspars, e.g., orthoclase $K[AlSi_3O_8]$

In Figure 16 the tetrahedral framework is thought to be composed of chains of a certain multiplicity. Another more common view is to

look at the polyhedra which form the framework, and the voids or polyhedral cavities generated between the framework oxygen ions. The notation $[5^{12}]$, for example, indicates a polyhedron composed of 12 pentagonal faces (a pentagon-dodecahedron); $[5^{12}6^2]$ is a polyhedron with 12 pentagons and two hexagons (see Fig. 17). According to the nature of the voids and polyhedral cavities tectosilicates can be divided into three groups [45–47]:

1) *Pyknosiles.* Tectosilicates which have no polyhedral cavities but small interstices between the framework oxygen ions; these voids can be occupied by cations and sometimes water: quartz, cristobalite, tridymite, feldspars.
2) *Clathrasils.* Tectosilicates with polyhedral cavities. The windows of the cages are small and the encaged ions, molecules, or their decomposition products cannot diffuse through them: melanophlogite, dodecasils, sodalite (→ Silica, Chap. 8.2.2.).
3) *Zeolites.* The polyhedral cavities are interconnected by large windows or tunnels, and the enclosed ions or molecules can diffuse through the crystal: analcime, mordenite, faujasite, zeolite A, silicalite (ZSM-5) (→ Zeolites).

Under hydrothermal conditions silica crystallizes from aqueous solutions as quartz, cristobalite, keatite, or coesite (→ Silica) [47,48]. In the presence of inorganic or organic guest compounds, clathrasils are formed. The neutral molecules become enclosed in the polyhedral cavities during synthesis. The guest compounds act as templates for the formation of the polyhedra, thus determining the type of clathrasil [46, 48]. Figure 17 shows polyhedra of melanophlogite and dodecasils occupied by guest molecules. The orientation of the molecules in the cages was derived from single-crystal X-ray diffraction [48].

Minerals of technical importance are the feldspars orthoclase $K[AlSi_3O_8]$, albite $Na[AlSi_3O_8]$, and anorthite $Ca[Al_2Si_2O_8]$ (Section 2.1). The largest amounts of feldspars (and nepheline) are used in the glass and ceramic industries, mainly as fluxes. Cordierite glass ceramics have good thermal stability and shock resistance (→ Glass Ceramics).

The most important synthetic tectosilicates are the zeolites (→ Zeolites) [49,50]. Their Si/Al ratio varies considerably. The most startling development was the synthesis of the almost Al^{3+}-free end members of silica-rich zeolites (ZSM-5 = silicalite-1, ZSM-11 = silicalite-2).

Figure 17. Guest molecules included in cages of the host framework of clathrasils

2. Natural Silicates

2.1. Feldspar

Feldspars [*68476-25-5*] are anhydrous alkali/alkaline-earth aluminosilicates that closely resemble each other in structure and properties. They are among the most common and important mineral groups, constituting ca. 60 – 65 wt % of the Earth's crust. Approximately two-thirds of them occur as plagioclases.

2.1.1. Structure and Composition

The feldspars are tectosilicates (framework silicates, see Chap. 1). The $[(Si, Al)O_4]$ tetrahedra are linked at all four vertices yielding a

framework $[Si_{4-x}Al_xO_8]^{x-}$. The voids within the tetrahedral framework contain alkali metal or alkaline-earth ions for charge compensation. The structure is composed of four-membered rings, $[(Si, Al)_4O_{12}]$, containing $(Al\,Si_3)$ or (Al_2Si_2) in each ring. The rings are linked by common oxygen atoms (two on each side) in the *a* direction to two neighboring rings to form zigzag bands (or "double crank-shaft chains") making use of three of the four common vertices. These bands are bonded in both the *b* and *c* direction by the fourth common oxygen atom of each (Si, Al) atom (see Fig. 18: in the *b* direction in $y = 0$ or 1/2, in the *c* direction in $y = 0.14$ or 0.36) to form three-dimensional tetrahedral frameworks. As a result, the (010) and (001) planes are rather weakly bonded and readily cleaved. This property is characteristic of all feldspars. The cations K^+, Na^+, and Ca^{2+}, and more rarely Sr^{2+} and Ba^{2+}, occupy the large spaces within the framework of tetrahedra, and are coordinated to oxygen in a fairly irregular manner.

Figure 18. Structure of orthoclase, projection parallel to *b* on (010) showing two crank-shaft bands along a_0

Three main types of feldspar ("molecules") can be distinguished:

1) $K[AlSi_3O_8]$ = potassium feldspar = orthoclase (Or)
2) $Na[AlSi_3O_8]$ = sodium feldspar = albite (Ab)
3) $Ca[Al_2Si_2O_8]$ = calcium feldspar = anorthite (An)

In nature, these three substances seldom occur in a pure state. At high formation temperature (e.g., in some volcanic rocks), a solid solution series between Or and Ab exists: the *alkali feldspars*. On slow cooling [i.e., in most plutonic (igneous) rocks] an immiscibility gap below 650 °C leads to partial unmixing (perthitization). Albite and anorthite form an almost infinite solid solution series: the *plagioclases.* Between orthoclase and anorthite a wide immiscibility gap exists (see Figs. 19, 20, 21).

Figure 19. Triangular phase diagram of orthoclase – albite – anorthite showing mixed crystal formation found in nature (at ca. 700 °C)

Figure 20. Phase diagram of the alkali feldspars

Pure potassium feldspar has the composition 64.8 wt % SiO_2, 18.3 wt % Al_2O_3 and 16.9 wt % K_2O. Potassium can be replaced by rubidium to a small extent, with the rubidium content in orthoclases from pegmatites reaching ca. 3 wt %. In the plagioclases, the Al_2O_3 content increases on going from the acidic to the basic types: from >19 wt % in albite to almost 37 wt % in anorthite with a concomitant decrease in the SiO_2 content from almost 69 wt % in albite to 43 wt % in anorthite.

Figure 21. Phase diagram of plagioclases (dry *mp* can be lowered by 500 °C in the presence of water)

All feldspars have a high- and a low-temperature form. In the high form, the distribution of $[SiO_4]$ and $[AlO_4]$ tetrahedra is at random, while in the low form there is a high degree of order. There are also intermediate types with varying degrees of Al/Si order. Ordering changes the monoclinic orthoclase to triclinic microcline. The high forms of albite and anorthite and of albite and orthoclase are completely miscible, whereas the low forms are not.

On slow cooling of the (K, Na) feldspars, segregation (perthite formation) takes place due to selective migration of the small and large cations (Fig. 20). This leads to a regular intergrowth of orthoclase (or microcline), and albite, with characteristic formation of string- or worm-shaped bodies, which can be macroscopic (macroperthite), microscopic (microperthite) or submicroscopic (cryptoperthite). Microcline – perthite consists of microcline containing albite strings, and antiperthite consists of albite with orthoclase strings.

The feldspars are very widely distributed, mainly in igneous rocks (volcanic and plutonic rocks) and metamorphic rocks (contact and regional metamorphites). They also occur in pegmatitic and hydrothermal formations, sedimentary rocks and sediments. This means that the petrographic classification of rocks is largely based on the mass ratios and compositions of the individual feldspars and quartz. If there is a deficiency of SiO_2, leucite $K[AlSi_2O_6]$ (see Section 2.3) or nepheline $Na[AlSiO_4]$ (see Section 2.2) is formed instead of the alkali feldspars.

2.1.2. Characterization of Individual Feldspars

The alkali feldspars can have monoclinic and triclinic crystal forms, but the plagioclases only triclinic forms. The most important feldspars follow.

Potassium Feldspars. The term *sanidine* denotes the metastable, glass-clear monoclinic high form of $K[AlSi_3O_8]$ with a random distribution of (Al, Si) produced by rapid cooling in volcanic rocks (volcanites). During the very slow cooling of plutonic rocks (plutonites) an Al/Si ordering takes place to a greater (triclinic microcline) or lesser (orthoclase) extent. Orthoclase is not visibly triclinized despite prolonged cooling in plutonites. Sanidine melts incongruently with separation of *leucite.*

Sanidine (the high-temperature form of $K[AlSi_3O_8]$) forms monoclinic – prismatic crystals, with space group $C_{2h}^3 - C\,2/m$; lattice constants: $a_0 = 0.856$ nm, $b_0 = 1.303$ nm, $c_0 = 0.718$ nm (a_0, b_0, and c_0 are somewhat smaller when sodium is present); the axial ratio is $a_0 : b_0 : c_0 = 0.657 : 1 : 0.551$; $\beta = 115°59'$; $Z = 4$ (number of chemical formula units per unit cell).

Orthoclase (the intermediate form of $K[AlSi_3O_8]$) forms monoclinic – prismatic crystals, with space group $C_{2h}^3 - C\,2/m$; lattice constants: $a_0 = 0.856$ nm, $b_0 = 1.300$ nm, $c_0 = 0.719$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.659 : 1 : 0.553$; $\beta = 116°01'$; $Z = 4$.

Orthoclase often consists of thick platelets parallel to [010], extended in the [001] direction or having columnar development in the [100] direction. Crystals may be several centimeters or even tens of centimeters in size. Twinning is very characteristic.

Microcline (the low-temperature form of $K[AlSi_3O_8]$) forms triclinic – pinacoidal crystals, with space group $C_i^1 - C\bar{1}$; lattice constants: $a_0 = 0.857$ nm, $b_0 = 1.298$ nm, $c_0 = 0.722$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.660 : 1 : 0.566$; $\alpha = 90°41'$, $\beta = 115°59'$, $\gamma = 87°30'$; $Z = 4$.

Barium Feldspars.

Hyalophane, (K, Ba) $[Al(Al, Si)Si_2O_8]$, forms monoclinic (or pseudomonoclinic?) crystals, with space group $C_{2h}^3 - C\,2/m$; lattice constants: $a_0 = 0.854$ nm, $b_0 = 1.298$ nm, $c_0 = 0.715$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.658 : 1 : 0.551$; $\beta = 115°35'$; $Z = 4$.

Celsian [*001302-50-7*], $Ba[Al_2Si_2O_8]$, forms monoclinic crystals, with space group I 2/c; lattice constants: $a_0 = 0.865$ nm, $b_0 = 1.313$ nm, $c_0 = 2 \times 0.730$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.659 : 1 : 2 \times 0.556$; $\beta = 115°02'$; $Z = 8$.

Plagioclases. The plagioclases form ca. 40 % of the solid crust of the Earth and are widely distributed. At high temperature (see Fig. 21) there is complete miscibility between the end members anorthite, $Ca[Al_2Si_2O_8]$ (basic) and albite, $Na[AlSi_3O_8]$ (acidic). At lower temperature, miscibility is incomplete. The plagioclases are usually twinned along [010], leading to lamellar replication multiple twinning, and typical striation.

The plagioclases have a structure similar to that of sanidine, the replacement of K^+ by the smaller Na^+ and Ca^{2+} ions leading to some deformation with triclinic symmetry. The low-calcium plagioclases [albite (An_{0-10}), oligoclase (An_{10-30}), and andesine (An_{30-50})] have a cell size similar to that of sanidine, with $C\bar{1}$ symmetry. The high-calcium plagioclases (labradorite (An_{50-70}), bytownite (An_{70-90}), and anorthite (An_{90-100})) show doubling of the c_0 lattice constant, so that bytownite has $I\bar{1}$ symmetry and anorthite $P\bar{1}$ symmetry. The plagioclases are usually characterized by the content (in mol %) of anorthite (An), albite (Ab), and orthoclase, whereby the content of orthoclase is usually negligibly small. An important characteristic of plagioclases is the degree of order, i.e., not only of (Al, Si), but also of (Na, Ca) and of (Na, Ca, K) in high-temperature mixed crystals containing potassium. The high- and low-temperature plagioclases can be distinguished optically. In the low-temperature plagioclases, there is an ordered distribution of (Al, Si). For example, in pure anorthite, which has no high-temperature form, the $[AlO_4]$ and $[SiO_4]$ tetrahedra alternate, whereby each oxygen is neighbored by an aluminum and a silicon ion. Despite the Al/Si disorder in high-temperature plagioclases, Al – O – Al groupings do not occur. Also, because the (Na, Ca) ions are smaller, the triclinic form is maintained at higher temperature, unlike sanidine. The triclinic high-temperature form of albite is also known as *analbite*. *Monalbite* is a monoclinic potassium-containing high-temperature phase of albite.

Albite, $Na[AlSi_3O_8]$, An_{0-10} or $Ab_{100}An_{00} - Ab_{90}An_{10}$; $C\bar{1}$ lattice constants: $a_0 = 0.814$ nm, $b_0 = 1.2789$ nm, $c_0 = 0.716$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.636 : 1 : 0.559$; $\alpha = 94°19'$, $\beta = 116°34'$, $\gamma = 87°39'$; $Z = 4$.

Oligoclase, An_{10-30} or $Ab_{90}An_{10} - Ab_{70}An_{30}$; $C\bar{1}$ lattice constants: $a_0 = 0.817$ nm, $b_0 = 1.284$ nm, $c_0 = 0.713$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.636 : 1 : 0.556$, $\alpha = 93°49'$, $\beta = 116°27'$, $\gamma = 88°59'$; $Z = 4$.

Andesine, An_{30-50} or $Ab_{70}An_{30} - Ab_{50}An_{50}$; $C\bar{1}$ lattice constants: $a_0 = 0.818$ nm, $b_0 = 1.288$ nm, $c_0 = 0.711$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.635 : 1 : 0.552$; $\alpha = 93°24'$, $\beta = 116°10'$, $\gamma = 90°24'$; $Z = 4$.

Labradorite, An_{50-70} or $Ab_{50}An_{50} - Ab_{30}An_{70}$; $C\bar{1}$ lattice constants; $a_0 = 0.816$ nm, $b_0 = 1.286$ nm, $c_0 = 2 \times 0.710$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.635 : 1 : 2 \times 0.552$; $\alpha = 93°34'$, $\beta = 116°06'$, $\gamma = 89°47'$; $Z = 8$.

Bytownite, An_{70-90} or $Ab_{30}An_{70} - Ab_{10}An_{90}$; $I\bar{1}$ lattice constants: $a_0 = 0.817$ nm, $b_0 = 1.287$ nm, $c_0 = 1.418$ nm $= 2 \times 0.709$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.635 : 1 : 1.102$; $\alpha = 93°22'$, $\beta = 115°58'$, $\gamma = 90°31'$; $Z = 8$.

Anorthite, $Ca[Al_2Si_2O_8]$, An_{90-100} or $Ab_{10}An_{90} - Ab_0An_{100}$; $P\bar{1}$ lattice constants: $a_0 = 0.818$ nm, $b_0 = 1.288$ nm, $c_0 = 1.417$ nm $= 2 \times 0.785$ nm; the axial ratio is $a_0 : b_0 : c_0 = 0.635 : 1 : 2 \times 0.550$; $\alpha = 93°10'$, $\beta = 115°51'$, $\gamma = 91°13'$; $Z = 8$.

2.1.3. Production

Feldspar can be synthesized by solid-state or liquid-phase reactions:

1) *Albite* is formed by heating a mixture of 1 mol Al_2O_3, 6 mol SiO_2, an excess of Na_2O, and sodium tungstate as a mineralizer at 900–1000 °C with a long reaction time (days).
2) *Orthoclase* is formed by heating a mixture of 1 mol Al_2O_3, 6 mol SiO_2, and a large excess of K_2O, with tungstic acid for mineralization at 900 – 1000 °C, or by heating a mixture of Al_2O_3, SiO_2 and acidic potassium tungstate at 900 °C. Crystals are obtained on treatment with boiling water.
3) *Anorthite* is obtained by fusing a mixture of Al_2O_3, SiO_2 and $CaCO_3$. The temperature is maintained slightly below the melting point ($\leq$ 1500 °C), and the mixture is slowly cooled. Four modifications (α, β, γ, and δ) are known.

Preparative methods using hydrothermal reactions in autoclaves or high-pressure reactors are also known:

1) Albite is synthesized by heating precipitated aluminum silicate and excess sodium silicate at ca. 500 °C
2) Orthoclase is synthesized by heating a mixture of Al_2O_3, SiO_2 and KOH with water in a ratio corresponding to $K_2O \cdot Al_2O_3 \cdot 6\,SiO_2$ at 400 °C, or from an aqueous slurry of potassium aluminate or $Al(OH)_3$ with potassium silicate in the presence of CO_2 at 360–400 °C
3) Anorthite is synthesized by heating a mixture of aqueous slurries of SiO_2, Al_2O_3, and CaO in the presence of $CaCl_2$ as a mineralizer at 470 °C

All synthetic feldspars are Al/Si disordered. Ordering requires geologic periods of time. Feldspars also occur in industrial products (ceramics). In synthetic feldspars, Si^{4+} can be completely replaced by Ge^{4+}, and Al^{3+} by Ga^{3+} or Fe^{3+}. This gives new end members that are only found as synthetic compounds. For example, δ-anorthite, δ-$Ca[Al_2Si_2O_8]$, which corresponds to natural anorthite, occurs in fly ash and sometimes in blast-furnace slags. It is formed when CaO- containing slags attack the chamotte (fire bricks) in blast furnaces and lime kilns.

The high-temperature form of albite, α-$Na[AlSi_3O_8]$, occurs in chamottes that have been exposed to Na_2O, e.g., in tank linings and checker bricks used in furnaces for glass-making.

α-Celsian, α-$Ba[Al_2Si_2O_8]$, is the principal component of special bricks used to line the arched roofs of the firing zones in electric tunnel furnaces for glazing stoneware and sanitary ware. It is very resistant to vapors from lead and borate glazes. Other refractory materials react with these vapors to form liquid phases.

2.1.4. Properties

Physical Properties. Feldspars can be glass clear, transparent, translucent, cloudy, matt, colorless, white, gray, or colored (e.g., greenish, reddish, red, or brown) due to inclusions. Labradorite and orthoclase can be iridescent (labradorescent) and are used for decorative purposes. The feldspars can have a glassy or sometimes nacreous luster. Fused feldspars, even if originally dark in color, usually solidify as a transparent, colorless glass.

Cleavage in the (001) plane is very good, moderate in the (010) plane, and just observable in the (110) plane [plagioclases also cleave in the (110) plane]. Orthoclase is named from the cleavages in the mutually perpendicular (001) and (010) planes. The plagioclases form triclinic crystals and owe their name to the fact that the angle between the (001) and (010) planes deviates by a few degrees from 90°. The fracture is conchoidal, uneven, and splintered or brittle.

The *Mohs hardness* of albite is 6 – 6 1/2, and of anorthite 6 – 7. *Densities* (g/cm^3) are: orthoclase 2.53 – 2.56, albite ca. 2.62, and anorthite ca. 2.76.

In thin sections, the feldspars show low refraction of light and birefringence (double refraction).

The average *specific heat* (J g^{-1} K^{-1}) of orthoclase between 0 and 100 °C is ca. 0.79, of albite 0.82, and of anorthite 0.80. The corresponding values for the range 0 – 1100 °C are 1.05, 1.1, and 1.12.

In the crystalline state the alkali feldspars become *electrically conductive* at moderate temperatures. *Ionization* is observed above 900 °C.

In the liquid phase, albite is one of the most strongly dissociated silicates.

The rate of *crystallization* in alkali feldspar melts is extremely small due to their high melt viscosity. The fusion range of natural orthoclase is 1140 – 1300 °C (incongruent melting, see also Section 2.3). Fused anorthite has a comparatively low viscosity, however, and crystallizes readily and rapidly on cooling to form large, well-formed crystals. The maximum crystallization rate occurs 20 – 25 °C below the temperature at which melting starts. A glass is formed only if the cooling rate is very rapid.

Chemical Properties. Chemical attack, including weathering, readily decomposes or changes the feldspars. The prolonged action of water on pulverized feldspar leads to preferential dissolution of the alkali ions, but also dissolves CaO and Al_2O_3, eventually giving a residue of polysilicic acids. Water containing dissolved CO_2 is more aggressive; alkali metals and Al_2O_3 are dissolved preferentially, and the reaction proceeds with formation of kaolinite ($Al_2O_3 \cdot 2\,SiO_2 \cdot 2\,H_2O$).

Strong mineral acids decompose alkali feldspars slowly, producing a residue of polysilicic acids. However, powdered anorthite dissolves completely in hydrochloric acid at 100 °C. Under high pressure (i.e., in autoclaves at ca. 200 bar) potassium feldspars are converted to kaolinite by 5 % hydrofluoric acid at 225 °C or by 0.5 – 1 mol/L HCl at 320 – 330 °C. This first causes complete hydrolysis of the starting material, followed by the formation of kaolinite and silicic acid. At lower temperatures, the reaction only produces a residue with a high silicic acid content. Anorthite is almost completely converted into kaolinite by treatment with 0.5 mol/L HCl at 340 °C.

Concentrated solutions of alkali hydroxide decompose the alkali feldspars completely above 110 °C. Reaction with 1 – 2 % solutions of alkali hydroxide leads to the formation of soluble products.

2.1.5. Mineral Deposits and their Extraction

The most important raw materials are the potassium feldspars (orthoclase, microcline), followed by sodium feldspar (albite). The other members of the plagioclase group are of very little value, although rocks with a high plagioclase content has been tested as a raw material for aluminum production. Nepheline syenite is industrially important (see Section 2.2), as are other rocks and sediments rich in feldspar (e.g., granites, syenites, and porphyries). Feldspar also occurs in some apatite deposits (e.g., in the Kola Peninsula, Russia). Furthermore, feldspar is extracted from sedimentary rocks (e.g., arkoses).

Economically useful deposits of high-grade feldspars are of limited occurrence. They are mostly plutonic rocks, pegmatites, and volcanic rocks with feldspar inclusions. When exposed, feldspathic rocks are often partially or completely kaolinized. Feldspar often arises as a byproduct during the processing of kaolin or mica. World production of feldspar is ca. 6.7×10^6 t/a (all weights specified are in metric tons).

The demands of European industry can be met from European deposits, the most important being in Italy, Turkey, Germany, France, Spain, the Czech Republic, Portugal, Russia, Norway, Sweden, Poland, Hungary, Finland and Greece.

The most important producers are Germany: Amberger Kaolinwerke, Hirschau; Birkenfelder Feldspatwerke Schweyer & Vollmer, Ellweiler; Gebrüder Dorfner, Hirschau; Kali-Chemie, Hannover; Keramische Rohstoffwerke Bauscher-Mandt, Weiden; Villeroy & Boch, Keramische Werke, Mettlach; Italy: Gruppo Maffei SpA., Milano; Minerali Industriali SpA.; France: Denain Anzin Minéraux (Feldspaths du Midi, Feldspaths du Morvan, Feldspaths Baux); Norway: Norfloat A/S; Spain: Unimin; Finland: Partek; Sweden: Svenska Forshammar AB, Gothenburg; Spain: Industrias del Cuarzo and Lansa; Turkey: Esan; Elginkam; former Soviet Union; United States: The Feldspar Corp., Spruce Pine/NC.; IMC Chemical Group Inc., Industrial Minerals Div., Boston/Mass.; Foote Minerals Co., Exton/Pa., Kings Mountain; Mica Co. Inc., Kings Mountain/NC.; Pacer Corp., Custer/SD.; San Antonio Mica Mine, Ajo/Ariz.; Mexico: Materias Primas Monterrey SA, Monterrey/N.L.; Argentina: Piedra Grande SA, San Luis; Japan: Kinsei Kogyo Co Ltd., Osaka; Morimura Bros. Inc., Tokyo; Nissho-Iwai Co. Ltd., Tokyo; Sumitomo Corp., Tokyo; India: Golecha Palawat & Co., Rajastan; Shree Modi Levigated Kaolin Pvt. Ltd., Rajastan; South Africa: Ceramic Minerals (Pty.) Ltd.,

Dunswart/Transvaal; General Overseas Traders S.A. (Pty.) Ltd., Johannesburg; Martin & Robson (Pty.) Ltd., Germiston; Otavi Mining Co. (Pty.) Ltd., Johannesburg; Rand London Corp. Ltd., Johannesburg; Rondebult Clayworks (Pty.) Ltd., Boksburg.

Opencast mining is used to extract sedimentary and pegmatitic deposits, although pegmatite is also obtained by underground mining. The usual methods such as drilling, explosives or cutting are used for massive rock deposits. Scrapers and front loaders are used for sedimentary deposits (loose rock), working in stepped faces.

2.1.6. Processing and Quality Requirements

Processing. Usually, processing of feldspar consists of crushing and/or grinding with subsequent classification, but some feldspar is also processed by flotation (e.g., feldspar in granitic rocks). The methods used to process the massive or loose rock depend on the end product, the mineral composition and the available equipment. In the simplest case, the feldspathic rock is progressively broken down by jaw crushers, ball mills, roller mills or pin mills; classified by vibratory sieves; washed if necessary; and dried. It is then ground using impact mills or ball mills to produce a coarse powder and classified by air elutriation. The final product contains not only feldspar, but also accompanying minerals (e.g., quartz or mica). Marketable products should have a favorable mineral composition with a high feldspar content. A quartz content of the product is not detrimental, since quartz is needed in any case for many applications (e.g., production of porcelain, glass and enamel). Any mica can be removed by air classification after breakdown of the rock. Accompanying minerals with a high magnetic susceptibility can be removed by magnetic separation. The content of heavy metal ions in the end product can be reduced to a safe level by this method.

The flotation process was introduced for processing feldspar in 1960 by the Finnish company Lohja Oy. The rock is first crushed, sometimes washed and dried and then ground. Mica, quartz, other accompanying minerals and feldspars are obtained in the froth or as a sediment in a series of flotation stages. Selectivity depends on the choice and dosage of reagents (activators, collectors, and foaming agents) and adjustment of the pH. Albite and potassium feldspar can also be separated from each other if necessary.

Feldspar also arises as a byproduct in the wet processing of kaolin. Quartz is first removed from an aqueous suspension of the crude ore. Kaolinite and feldspar are then separated in hydrocyclones, dewatered, and dried with rotary or tray dryers (→ Clays, Chap. 4.1.2.). The degree of separation (feldspar : quartz ratio) is ca. 9 %.

In another process, the kaolinite and accompanying clay minerals are slurried, and the feldspar – quartz concentrate (particle size 0.1 – 0.5 mm) is separated into feldspar and quartz by an electric field of 40 kV. The degree of separation (feldspar : quartz ratio) is ca. 96 %. High-intensity magnetic separators are used to remove paramagnetic impurities. Grinding is performed in nonferrous equipment and is followed by air elutriation, giving products with a maximum grain size of 40 – 150 μm.

Quality requirements vary considerably and depend on the end product consumer. High-quality products generally require high-purity raw materials of defined composition. For white glasses, light-colored ceramics, glazes and enamels, the content of heavy metal ions must be extremely small (≤ 0.08 wt %). Contents of Na_2O and/or K_2O and Al_2O_3 must be specified to ensure satisfactory physical and chemical properties, especially strengths of glasses. When the products are used as fluxes, the alkali oxide content must be increased to bring about the desired reduction of the melting point. Important quality criteria for some applications are the particle size, the particle size distribution, and the tolerance range for the fractions of over- and undersized particles.

Chemical and physical data of some feldspar grades are given in Table 5; some particle size distributions for feldspar sands and powders are given in Tables 6.

2.1.7. Uses and Economic Aspects

The glass and ceramic industries are the main consumers of sodium and potassium feldspars and also of related minerals of lower quality

with respect to heavy metal ions and accompanying minerals (i.e., feldspathic pegmatites, aplites, phenolites and Cornish stone). See also → Glass, Chap. 5.1., → Ceramics, General Survey, Chap. 2.4. The alkali feldspars have a fluxing action due to their alkali-metal oxide content. They reduce the temperature at which melting begins (i.e., the sintering point of the raw material mixture) and thus shorten the time required for melting or firing. This reduces energy consumption and increases production capacity and the life of the refractory linings. On cooling the melt, the oxidic components of the feldspar form a glassy structure, which provides the glassy matrix in ceramic products.

Al_2O_3 increases melt viscosity, facilitating mechanical forming of the glass. It also increases hardness and impact strength (toughness) and prevents crystallization (devitrification). In ceramic masses, the Al_2O_3 in the glassy matrix reduces the tendency to fire cracking and increases impact strength.

Sodium feldspar is usually added at a level of 0.2 – 17 wt % as a raw material for glass. Potassium feldspar is generally employed for ceramic products, although sometimes calcium or calcium/sodium feldspar is also used.

Feldspar (admixtures of 4 – 20 wt %) is used in the coating for arc-welding electrodes to improve the flow of the molten slag. In blast furnaces, the addition of feldspar also improves slag flow during tapping.

Powdered feldspar is used as a mild abrasive due to its hardness, conchoidal fracture and platelet-shaped particles. Light- colored alkali feldspars, anorthite and plagioclase are added to coatings in the form of fine sands or coarse powders to give antiskid properties to floor coverings and surfaces intended for vehicles and pedestrians.

Finely ground feldspar grades are good fillers for exterior paints because of their chemical inertness, lack of photoreactivity and good dry brightness. As a filler feldpsar competes with other, often cheaper, raw materials such as calcite and dolomite. They are also used as fillers for pigments, adhesives, rubber (especially foam rubber), thermoplasts and thermosets. They can be used as fillers in large amounts approaching the critical pigment volume concentration (CPVC), giving transparent or nearly transparent paints and polymer products, because the refractive indices of many paint resins, plasticizers and polymers are almost the same as those of the feldspars ($n \approx 1.55$).

Feldspathic rocks that can be dressed are also used as building stone, as hard core in roads, and as bright, reflective chippings in bitumen-bonded road surfaces.

In Western Europe, the approximated total consumption of feldspar is ca. 3.7×10^6 t/a and is divided as follows:

Ceramics	57 %
Glazes and enamels	4.5 %
Glass	34 %
Abrasives	1.5 %
Fillers	0.4 %
Others	2.6 %
